In 1941 a group of United States physicians generously provided the Ministry of Health with several millions of multi-vitamin capsules. With these, feeding tests were carried out on factory workers and school-children in 1941–2 and 1943–4. The first test was done on 1,242 school-children in London, Ipswich, Glossop, and a camp school, and on 214 men working in smelting furnaces; it lasted 6 to 12 months, half the subjects receiving one vitamin capsule on 5 to 7 days of each week. Each capsule contained about an adult's daily needs of vitamins A and D and of aneurin, riboflavin, niacin, and ascorbic acid. Since the national diet was thought to provide a sufficiency of all nutrients, including vitamins, the groups receiving the capsules were believed to be consuming the vitamins in excess of requirements to the extent provided by the capsules. Therefore the feeding tests were a trial of excess of vitamins, unless our estimates of their amounts in the national diet were over-optimistic. In this event, the vitamins, by making up the deficiencies would be expected to show some discernible effects. Inequalities in the nutritive values of the home diets were controlled by random division of the subjects, according to age and sex, into control and vitamin groups.

The second test was done in 1943–4 on 1,620 children aged 5 to 14 years in Stoke-on-Trent and Salford, and lasted for 12 months. The procedure adopted was the same as that in the first test. In the second test the diets of the children were specially surveyed. The results obtained showed no appreciable differences in the nutritive value of the diets between the groups.²⁰

Results of Feeding Tests.—The results of both tests were similar.^{21, 22} In the factory workers the vitamin supplements were without effect on weight, haemoglobin, blood pressure, morbidity, or output of material. In the school-children the vitamins had no consistent effects on growth, strength, endurance, hearing, incidence or severity of a variety of clinical criteria, general nutritional state, or absence from school through illness. The vitamins had, however, an apparently beneficial influence, just statistically significant, on gingivitis in the Stoke children, but not in the Salford children or in the children or adults in the first test. Two considerations must be mentioned: (1) the vitamin groups of children in Stoke, by chance, had initially higher proportions affected with gingivitis than the corresponding controls; and (2) the beneficial influence was most apparent after the first three months, but was not fully sustained for the remainder of the test. In view of these facts of the absence of effect of the vitamins on the gums in the first test and in the Salford children in the second, it would not be justifiable to interpret the Stoke findings in other than a narrow and restricted sense.

Other Vitamin-feeding Tests.—The findings in the important vitamin-feeding tests done in recent years have been reviewed.²³ Only those carried out during the war in this country, where the basic diet was roughly the same, are strictly relevant. Weighing up all the relevant feeding trials with vitamin supplements, the results do not show any consistency. There can therefore be no certainty that large-scale additions of vitamins to our wartime diets would have improved their nutritive value. The decision of the Ministry of Health to resist the many requests to recommend the issue of vitamins as a prophylactic measure has therefore been justified. The decision was based on careful estimates made in the early months of the war—estimates which were an integral and essential part of the wartime food plans.

Vitamins as Therapeutic Substances.—Since their isolation and synthesis, the better-known vitamins have been used in curative medicine not only for the treatment of specific deficiency states—e.g., vitamin D in rickets—but also, and to an increasing extent, for their supposedly general tonic effects. In some instances, as in the use of aneurin for neuritis or sciatica, some

semblance of rational therapy might be argued, but more generally the underlying theory would seem to be—Since a little of the vitamins does some good then a lot of them will do more good. This is not to despise every therapy that is not based on physiological or pharmacological research, for the clinician cannot always wait on the results of the experimentalist. Indeed, many advances in physiology have originated in the successes and failures of the clinician. Scurvy, for instance, had been robbed of its terrors for sea-going folk long before vitamins had been heard of. Whether the administration of pure vitamins, in an irrational and blunderbuss fashion, is worth while is a question which the clinician must answer for himself. There are, however, some recent additions to our knowledge which may assist him.

Frankau⁴⁸ subjected groups of R.A.F. men to a test involving speed, stamina, and co-ordination. After giving each man 50 mg. of niacin, alone or with other vitamins, daily for a few days, the men performed the test with greater skill and efficiency. It should be noted that (a) the basic diet of the men was excellent, (b) the men were very fit, (c) the dose of niacin was four to five times the daily requirements, and (d) the effects became manifest after a few days. Borsook⁴⁹ gave 528 men working in an aircraft factory on every working day for a year 50,000 i.u. of vitamin A and correspondingly large amounts of vitamin D, riboflavin, niacin, ascorbic acid, and calcium. He found that work was more efficient and that absences through illness and other causes were significantly reduced. He calculated that each worker saved on an average 10½ days' work in the course of a year. In this test the workers were receiving a great excess of vitamins—to the extent of about 10 times the daily requirement. Frankau believed that the effects of niacin in her tests were pharmacological; very probably those described by Borsook were of the same order.

Ultimate Effects of Excess of Vitamins.—The public health specialist is entitled to ask what the ultimate effects would be on the health of men and women taking vitamin supplements at high levels for the whole of their lives, and on the health and development of their children. Many are of the opinion that, at of colossal doses, vitamins can do no harm. Some recent researches, however, cast doubt on the wisdom of this.

Richards⁴⁵ found that the addition of a small supplement of aneurin to rats fed on a diet low in the B complex vitamins, but not so low as to cause signs of deficiency, produced unmistakable evidence of deficiency of other factors of the B complex in the next generation, but not in the parent rats. These findings have, in general, been confirmed by Pett *et al.*⁴⁶ Leitner,⁴⁷ after treating two patients for some time with large doses of B₁, found that one developed symptoms of thyrotoxicosis and the other of anaphylaxis. Foster *et al.*⁴⁸ found that mice fed on adequate diets supplemented with aneurin became more susceptible to poliomyelitis virus than controls.

Nutritional Status

The systematic clinical surveys which the Ministry of Health has been conducting since 1942 give a picture of the nutritional state of the public as a whole.^{49, 50, 51} These have shown that the general standard of nutrition of the population has been maintained at a high level during the war. It is remarkable that, after six years of rationing and of war, out of 20,235 people examined only 9 were found to show evidence of deficiency disease, only 0.7% were of "poor," and only 10.5% of "fair" nutritional state. The returns of the Ministry of Education support this evidence; the percentage of children for England and Wales found to be below normal was 11.3 in 1938 and 9.7 in 1944.

The systematic surveys were conducted by Dr. Sydenstricker in 1942, using the procedure developed by him in the U.S.A., and later by Drs. Hawes, Stannus, Adcock, and Fitzgerald, all of whom had had much previous experience of deficiency disease. All possible care was taken to ensure uniformity of method and of standards. Frequent consultations on the same subjects took place from time to time, and two clinicians usually worked together. The procedure consisted in a search for evidence of deficiency disease and then of an assessment of nutritional status—the slit-lamp, special tuning-fork, and other clinical aids being used.

The clinical method has its critics, but there is none other which would serve the purpose the Ministry had in mind. The other procedures that have been suggested are anthropometry and biochemical and physiological measurements. These can be regarded only as adjuncts to the clinical method; for by themselves they tell us little. The reports of nutritional surveys of undernourished people in Europe that have come to hand, many including biochemical analyses, seem to have been singularly unproductive on the basis of the biochemical results alone; the clinical findings, on the other hand, were always of value. The time is not yet ripe for full discussion of this difficult subject, and it is to be hoped that the reports of the European and Eastern experiences, when they become available, will help to solve some of its many problems.

Two clinical conditions—follicular keratosis and corneal vascularization, the one observed frequently, the other rarely, in clinical surveys—require further discussion.

Follicular Keratosis

Follicular keratosis, or folliculosis, is found in as high a proportion as 30% of older school-children and adolescents, less frequently in younger children, and rarely in children under 5. The presence of the condition bears no apparent relation to the general nutritional state. It is found frequently in healthy adolescents of both sexes, particularly in girls; it is very common in children leading a healthy open-air life, and is seen more often in winter than in summer. Female adolescents in a sausage factory showed no evidence of the condition, whereas a high proportion of girls of the same age in factories in the same district were affected. This suggested that the presence of animal fats on the skin prevented the development of the condition. Hawes and Stannus then conducted feeding tests lasting for three months or more on several hundreds of children and adolescents in institutions and schools. They used preparations of vitamin A in high concentration (so as to avoid possible effects of fatty acids), ascorbic acid, nicotinamide, pantothenic acid, and a special preparation of maize oil rich in unsaturated acids considered to be essential—viz., linoleic and linolenic acids. These were given by mouth in the following doses: vitamin A, 10,000 i.u.; ascorbic acid, 50–100 mg.; nicotinamide, 50 mg.; pantothenic acid, 50 mg.; and maize oil, 0.75 ml. per day. No definite effect could be attributed to any of the substances, but maize oil in some cases seemed to cause a softening and diminution in size of the follicular projections. Pantothenic acid seemed to have a slight effect on the follicles in some cases, but none of the other substances had any discernible action. Vitamins A and C were given very extensive trials, but no effect of any sort was observed. Deficiency of vitamin A or vitamin C was evidently not the cause. Stannus⁵² has suggested that the condition is not nutritional in origin, but is identical with keratosis pilaris or lichen pilaris, which is generally believed to be unimportant. Zieler⁵³ says of it: "Das Leiden hat keine besondere Bedeutung (Schönheitsfehler)"—"a beauty blemish," is all he thinks of the condition.

In Stannus's view the follicular keratosis, or phrynodermia, said to be pathognomonic of vitamin A deficiency is nothing more than an exaggerated and more generalized keratosis pilaris, which by itself means nothing in a nutritional sense.

Corneal Vascularization

The earlier view that corneal vascularization is pathognomonic of riboflavin deficiency has been shown to be too sweeping—just as much so as the inferences drawn from defective dark-adaptation relative to vitamin A deficiency in the early days of that technique. Ariboflavinosis has been reported in as high a proportion as 99% of subjects examined.⁵⁴ Subsequent observations by a number of workers have made it clear that the corneo-scleral junction is not avascular, as was formerly thought, and that the pathological pattern of the vessels is not easy to distinguish. Deficiency of riboflavin is not the only cause of vascularization of the cornea; exposure to bright light, heat, and cold also cause it. The subject was discussed by Stannus in his Lumleian lectures⁵⁵ and by Ferguson.⁵⁶ Both are of the opinion that vascular changes in the cornea due to riboflavin deficiency are rarely encountered in this country at present.

Intravenous Alimentation

The theoretical basis of intravenous alimentation is quite rational. It consists in the administration by vein of sufficient metabolizable nutrients to keep the body going and to repair damaged tissues when the body is unable to absorb food taken by mouth. The treatment would seem to be indicated in any condition in which absorption of enough nutrients cannot be achieved. There would seem, however, to be an overriding condition for the adoption of treatment—viz. the circulating blood should be of sufficient volume and rate of flow to sweep away rapidly the injected material so as to obviate local accumulation and thrombosis. Until about 1938 intravenous alimentation was confined almost entirely to the administration of glucose and saline solutions. Elman and Weiner¹ first reported the use of protein hydrolysates for the treatment of patients suffering from inanition arising out of, or as a complication of, a variety of pathological states. In 1943 Elman and Lischer² reported much success for the treatment in several hundred cases. Elman claimed that his preparation rarely if ever caused reactions, but the same could not be said of other preparations, most of which gave rise to reactions of an anaphylactic type. The subject has been reviewed by Elman,³ Gaunt,⁴ and Cuthbertson.⁵

The most successful of all the American preparations is amigen. The British preparations for intravenous use are made by hydrolysing casein with sulphuric acid. This breaks down the tryptophan which has to be added to ensure the "vollwertigkeit" of the preparation. Sometimes supplements of cystine and methionine are also added.

Scope for extensive use of these preparations seemed likely to develop with the prospect of starvation in Europe at the end of hostilities. In starvation there is progressive failure of digestion and absorption and when the stage of dehydration is reached, both of these functions would seem almost to have ceased because of degeneration of the intestinal mucosa.⁶ It is then that intravenous alimentation appears to be most appropriate, if for no other reason than that food of any sort given by mouth to people in such a debilitated state tends to increase the diarrhoea and dehydration. In the German horror camps, after liberation, a number of people were treated by intravenous alimentation, but the results were far from being uniformly good. The treatment evidently met with greater success in the Bengal famine of 1943.⁷ Doubtless lack of adequate nursing was a cause of failure, as Vaughan and others⁸ have pointed out, but many of the subjects were evidently unsuitable. A circulation of sufficient vigour to ensure rapid dispersal of the nutrient fluid throughout the body and the prevention of local thrombosis is evidently indispensable for success. For this reason, restoration of the circulation by transfusions of plasma, serum or whole blood would seem to be an essential preliminary to the adoption of intravenous alimentation in starving people.

A few repatriated prisoners of war were treated with protein hydrolysates in England in 1945 with some, but not spectacular, success. Although no untoward reactions were reported, thrombosis of injected veins occurred in every case.

Conspicuous by contrast is the success of treatment with amigen in the U.S.A. A recent paper by Brunschwig and others⁹ provides an example. They kept alive a man aged 50, who had had two major operations, for 56 days on amigen and glucose by vein, no other nourishment of any sort was given. The man recovered completely. A fully satisfactory preparation could probably be put to wide clinical use. Treatment should obviously be restricted to persons unable to absorb food taken by mouth, and it should give way to ordinary feeding as soon as there is reason to believe that absorption is restored.

Oral Hydrolysates

An enzymic digest of protein not so fully broken down as the acid hydrolysate was also used in Europe for the treatment of starvation.¹⁰ Little success was obtained. There are two objections to these semi-digested preparations. The first is that the stuff is too nauseating, and the second that there is no physiological basis for such a half-way measure between ordinary feeding on the one hand and intravenous feeding with metabolizable nutrients on the other. For anatomical reasons

impairment of digestion is hardly conceivable without impairment of absorption. Therefore, if a patient cannot digest food he is not likely to be able to absorb it either.

Summary and Conclusions

The wartime food policy was the first large scale application of the science of nutrition to the population of the United Kingdom. This application was brought about by home production and importation of suitable foods in suitable amounts, by rationing according to needs, by subsidies on staple foods, and by adequate wages. A diet more than ever before in conformity with physiological requirements became available to everyone, irrespective of income.

The other environmental factors which might influence the public health had, on the whole, deteriorated under the stress of war. The public health, so far from deteriorating, was maintained and even in many respects improved. The rates of infantile, neonatal, and maternal mortality and the stillbirth rate reached the lowest levels ever. The incidence of anaemia declined, the growth rate and the condition of the teeth of school-children were improved and the general state of nutrition of the population as a whole was up to or above pre-war standards. We are therefore entitled to conclude that the new knowledge of nutrition can be applied to communities with the expectation that concrete benefit to their state of well being will result.

The national diet showed, however, some significant departures from physiological requirements, especially with respect to milk and bread. Consumption of milk was not more than about 75% of the desirable amount. In regard to bread, the defect was removed by the adoption of a higher milling ratio of wheat in 1942. The subsequent lowering of the ratio reduced the nutritive value of bread, but, so far as our present knowledge goes, the 80% ratio is about sufficient to ensure enough B vitamins for the metabolism of carbohydrate in bread. It is, however, questionable if it would suffice for the metabolism of additional unbalanced carbohydrate such as would follow a large increase in the consumption of sugar, unless consumption of other vitamin B rich foods—e.g., milk and eggs—were correspondingly increased.

If we are to retain what has been achieved during the war we must see that the quality and quantity of our agricultural produce and imports are determined primarily by health requirements and that, when, in the fullness of time, free choice of food returns the public are made aware of the dietary requirements for health. Steps should also be taken so to arrange our social and economic affairs as to make it possible for everyone to secure a diet sufficient for his needs.

The need for up-to-date information about food distribution and the nutritional state of the public will continue. Accordingly, surveys of food consumption and of the nutritional state of samples of the population should be carried out from time to time. The technique of dietary surveys is now fairly well established, but that for surveys of the nutritional state is much less satisfactory. More research requires to be done, involving laboratory and clinical studies, therapeutic tests, and feeding tests. Among subjects worthy of study are the significance of haemoglobin levels, and of a variety of commonly occurring signs and symptoms of a minor order, such as gingivitis, pyriasis sicca, and corneal vascularization, and the relationship of diet to the incidence and progress of disease, including dental disease. The perfection of preparations of protein hydrolysates and of the technique of administration would open up a wide field for their use in curative medicine.

I wish to express my sincere thanks to Mr Shrimp on and Mrs Corder, of the Ministry of Food, who generously placed at my disposal data of family diets and of body weights, and who assisted me with certain computations.

TREATMENT OF CHEST WOUNDS IN FORWARD AREAS

A REVIEW OF 100 CASES

BY

W. MICHIE, M.B., B.Ch., F.R.C.S.Ed.

Major, R.A.M.C.; Surgical Specialist at a Casualty Clearing Station

H. W. C. BAILIE, M.B., B.Ch.

Capt., R.A.M.C.; Officer Commanding a Field Transfusion Unit

AND

J. MACPHERSON, M.B., B.Ch.

Maj., R.A.M.C.; Officer Commanding a Field Transfusion Unit

(From British Liberation Army)

Chest wounds comprise a considerable section of the injuries of war, and the importance of their early treatment is now generally recognized. A series of 100 consecutive cases treated at a casualty clearing station (C.C.S.) is reviewed.

Statistical Survey

Undoubtedly many chest casualties die on the battlefield, and further deaths occur before surgical aid is available. Those surviving at C.C.S. level represent a varying proportion of the total casualties admitted, as shown in Table I. Of the 220 cases analysed the 100 reviewed in this article were all dealt with by one surgical unit.

TABLE I.—Analysis of 220 Cases

	Cumtort Wounds	Shell Wounds	Mortar Wounds	Bomb Wounds	Grenade Wounds	Mine Wounds	? Wounds	Missile	Total	Total Admissions	% of Total
July	19	10	28	—	—	—	—	—	57	905	6.3
Aug.	15	9	20	—	—	—	—	—	45	611	7.3
Sept.	16	4	6	—	1	—	—	1	30	424	7.0
Oct.	20	30	6	2	—	2	—	3	63	1,096	6.0
Nov.	3	10	—	—	—	—	—	—	20	560	3.5
Dec.	3	1	—	—	—	—	—	1	5	428	1.2
Totals..	76	64	62	2	3	4	9	—	220	4,024	

July, August, September, and October were active battle phases when an attached field dressing station filtered off light

and walking wounded, passing only the more serious cases to the C.C.S. During this period the incidence of chest wounds was in the region of 6.6%. In November there was a fall to 3.5%, due to seasonal increase in medical cases. In December the C.C.S. took casualties without filtration, and the rate was only 1.2%. The overall rate, including the numbers filtered off, for the period July to December was 2.7%. This is an increase of 40% over comparable figures for the last war (War Office Publication, 1944), and may be due to such factors as improved first aid, more rapid evacuation, and higher priority in treatment.

The proportionate incidence of wounds due to various causative agents changed during the progress of the campaign. In Normandy mortar wounds accounted for a relatively high proportion. During the advance into the Low Countries small arms wounds were predominant. In November and December when contact with the enemy was limited to patrols, shellin accounted for most of the wounds. Aerial bombs, mines, and grenades did not at any time cause many casualties. There was no instance of wounding by bayonet or knife.

Types of Wounds.—Chest wounds are of four types. The non-penetrating wound does not enter the pleural cavity; the penetrating wound has an entry only; the perforating wound traverses the chest, with entry and exit. In the thoracic abdominal or abdomino-thoracic injury the same missile passes either through the chest into the abdomen or in the reverse direction. Any of these types penetrating the pleura may give rise to a sucking wound.

First-aid Treatment

Treatment begins on the battlefield. The stretcher-bearer work demands brawn more than brain, but with a little training he is capable of doing a great deal for chest casualties. The marked dyspnoea caused by a penetrating chest wound is easily recognized; the stretcher-bearer may be able to plug a large sucking wound with a field or shell dressing. Distress and anxiety should be relieved by morphine, and the stretcher-bearer can give 1/4 gr. (16 mg.) intramuscularly into the thigh or shoulder by means of a "syringe." Subcutaneous administration is of little value, since peripheral circulation in chest wounds is quickly impaired and absorption from the tissue delayed. All patients with chest wounds should be stretcher-borne, preferably with the head and shoulders elevated by high cushion of blankets or clothing.

When the patient reaches the aid post the regimental medical officer is able to examine the wound more carefully and apply the proper dressing. As many wounds begin to suck at a late stage it is safer to treat every penetrating wound as a potential "sucker." The skin around the wound is cleaned of blood and sweat, and a pad of vaselined gauze, plugged into the wound if necessary, is covered with a field dressing and held firmly in place by a generous application of adhesive strapping, which completes the seal. Elastoplast is unsuitable because it tends to stretch and "sweat off." If the patient has not yet had morphine it should now be given by the medical officer—intravenously, if possible.

The principles of first-aid treatment adopted by the R.M.C. also hold in the field ambulance. Dressings, if still satisfactory, should not be disturbed, and the average patient, after a short rest, is able to continue his journey to the C.C.S. If dyspnoea continues to be severe it may be due to persistence of "suck." For the majority re-dressing may suffice, but for large wounds this may be inadequate. In these circumstances the skin edges can be approximated by a single suture over vaselined gauze pack. This is a temporary measure only, to enable evacuation to the C.C.S., where normal surgical procedure then takes place. Where respiratory distress is severe and respirations are shallow, oxygen by B.L.B. mask is of value. If it is necessary at the field ambulance it should be continued during the journey to the C.C.S.

Transfusion for chest injuries at field ambulance level is of debatable value. Transfusion produces its best results when closely allied to surgery, and if the patient is transfused forward the improvement in his general condition is usually nullified by the journey to the C.C.S. Pre-operative transfusion in these cases is then found to be more difficult, and the patient responds more slowly than he would if he had been evacuated without

preliminary transfusion. It is permissible if evacuation is delayed or the journey is a long one, but such circumstances were rare in this campaign.

Pre-operative Treatment and Diagnosis

On arrival at the C.C.S. the patient is admitted to the resuscitation ward and propped up on a back-rest. Enough clothing is removed to allow a rapid but careful scrutiny of the chest wall. Some wounds are now found to be sucking, either because the dressing has become loose or because "suck" has developed in a wound which appeared closed at the field ambulance; these require immediate sealing. Traumatic emphysema may be present. It indicates a penetrating wound, and may be extensive, causing gross swelling as far as the neck and face and extending down the abdominal wall to the groins. It is often associated with a small skin-entry wound. Evidence of pneumothorax must now be sought. The most helpful signs are displacement of the apex beat and deviation of the trachea. Tension pneumothorax is uncommon, but must be excluded. It is rarely seen at the C.C.S., only two cases having been observed in over 5,000 admissions. Cases have, however, been reported from forward areas, and it is possible that this may account for some deaths soon after wounding. Tension pneumothorax results from leakage of air from terminal bronchi and bronchioles into the pleural cavity, whence there is no escape to the exterior. The condition is progressive and treatment urgent. A wide-bore needle is inserted into the second interspace anteriorly and a one-way flow provided by reversing the air-inlet valve of an Army pattern transfusion set.

During rush periods routine radiography is not possible. Some indication of the route of the missile can be gained by an appreciation of the position of the patient relative to the bomb or weapon which injured him. The value of early radiography lies mainly in a knowledge of the final position of the foreign body. Skiagrams of the chest and abdomen should always be taken when there is a possibility of thoraco-abdominal injury. It is not necessary in through-and-through wounds.

Diagnosis of thoraco-abdominal injury may present considerable difficulty. Chest wounds alone can cause abdominal rigidity and sometimes abdominal pain, either from irritation of the diaphragmatic pleura or from spinal or intercostal nerve involvement. Rigidity in a penetrating abdominal wound can be variable, depending on the extent of haemoperitoneum or bowel injury. Clinical differentiation of thoraco-abdominal from pure chest injury may be impossible on purely clinical grounds, and in cases where radiological evidence is not conclusive the final diagnosis may be possible only at operation.

Transfusion

For statistical purposes the cases under review have been divided into four groups: (A) Penetrating and perforating chest wounds uncomplicated by other major injury. (B) Penetrating and perforating wounds with associated major injury. (C) Thoraco-abdominal wounds. (D) Non-penetrating wounds of the chest with or without associated major injury.

TABLE II.—Numbers of Cases Transfused in Different Groups

Group	Total Cases	Transfused	Total Blood (pints)	Total Plasma (pints)
A	23	4	11	2
B	37	19	47	12
C	22	18	60	7
D	18	9	23	4
Totals ..	100	50	141	25

Of the 100 cases, 50 were transfused with an average of 3.3 pints (1.9 l.) of protein fluids. The proportion of blood to plasma used was in the ratio of 11 to 2. Of the four cases transfused in Group A, two had severe intercostal bleeding, each requiring three pints (1.7 l.) of blood, one previously having had two pints (1.14 l.) of plasma at a field ambulance. A third, with a fractured sternum, had one pint (568 ml.) of blood only. The fourth was critically ill on admission, and, despite transfusion with four pints (2.27 l.) of blood, died suddenly during induction. In Groups B and D transfusion rates are similar—an indication that transfusion was required mainly on account of associated injury. This is borne out by the low transfusion rate in Group A. The fact that 18 cases out of 22 in Group C

were transfused is merely an indication of the high incidence of involvement of liver, spleen, and kidney in thoraco-abdominal injuries. Group D includes two known cases of blast-lung. In theory such cases should not be transfused, but since they had very severe associated injuries it was felt that transfusion should not be withheld, for without it they had no chance of recovery.

Transfusion of cases with intrathoracic injury has until recently been regarded with disfavour. It was argued that overloading of the right heart and pulmonary oedema might result and that bleeding from the lung might increase. This has not been observed even in cases receiving as much as seven pints (4 l.) of blood. The response to transfusion does not seem to differ from that in any other type of injury. Transfusion of two to three pints (1.14–1.7 l.) at the rate of 15–20 ml. a minute appears to be well tolerated.

Operative Treatment

No operative intervention is necessary in small penetrating wounds which are not sucking, and these cases may be passed direct to the physician.

A few cases reach the C.C.S. *in extremis*. This may be accounted for by intrathoracic haemorrhage due to hilar or mediastinal damage, but more often inspection shows that because of its site or extent closure of a sucking wound has not been effective. The urgent need is stressed for closure of the wound as a primary measure. Insertion of muscle sutures without an anaesthetic may be necessary before attempting resuscitation. These cases have operation priority second only to severe uncontrolled haemorrhage, and take precedence over all else in the resuscitation ward.

Cases requiring operation have lacerated wounds with comminution of the adjacent ribs. Bleeding is often profuse, and may originate from intercostal or internal mammary vessels and less often from lacerated lung tissues. Operative procedure in the C.C.S. is essentially minimal. In cases with associated injuries the penetrating chest wound is dealt with first. Under gas-and-oxygen anaesthesia the wound edges are excised and devitalized tissues and rib fragments removed. Rib ends are trimmed beyond the edges of healthy pleural tissue so that no possibility remains of subsequent laceration of the lung. Any intercostal haemorrhage is dealt with by a through-muscle suture. The anaesthetist then expands the lung so that the injured area presents in the wound. Lacerations can be sewn up and bleeding controlled, but interference with lung tissue is rarely necessary. Foreign bodies, if readily accessible, are removed, but systematic searching is unwise, since it tends to embarrass still further a mechanically laboured respiration. Possible exceptions to this rule are foreign bodies known to be in the region of the hilum or pericardium. The pleural cavity is then sucked dry and 50,000 units of penicillin introduced in 5–10 ml. of normal saline. The wound edges are dusted with penicillin-sulphanilamide powder and, with lung expansion maintained to the full by the anaesthetist, the pleura is closed—separately, if possible, but generally by incorporation with muscle tissue. Careful approximation of muscle layers is essential to prevent further leakage. Where there is extensive tissue loss it may be necessary to swing a flap of muscle from the pectorales or the latissimus dorsi to obtain closure. When cases can be held at least six days, suture of the skin is permissible.

Thoraco-abdominal Wounds

The incidence of thoraco-abdominal wounds to total chest wounds has been given variously as from 6 to 14%. In this series the figure is 22%. The difference is explained by the transference in Normandy, where lines of evacuation were short, of uncomplicated penetrating chest cases back to base for treatment.

Expectant treatment is the normal procedure where the skiagram shows a small foreign body lodged in the liver from a right-sided chest wound, and no attempt should be made to remove it. In the majority of cases the wound of entry is in the lower chest, the tract proceeding horizontally through the diaphragm and involving upper abdominal organs. In some it is directed downwards and may injure any of the abdominal contents. The operative approach depends on the site of the entry wound. As diagnosis is often confirmed by following the track of the wound it is generally expedient to use an incision

starting at the point of chest entry, running downwards and forwards towards the upper abdomen along an intercostal space. By this approach exposure of the diaphragmatic wound and left upper abdomen is adequate, and many forward surgeons have commented on the ease with which splenectomy can be carried out by the transthoracic route. Further advantages are easy repair of the diaphragm and the avoidance of confirmatory laparotomy in doubtful cases where the peritoneum is found to be intact.

In the series under review there were 22 cases of thoraco-abdominal injury. One case was treated expectantly and 21 were submitted to operation. The principal abdominal organs involved were: liver (11), spleen (7), kidney (7), stomach (3), jejunum (2), and colon (1).

Post-operative Treatment

The post-operative treatment of chest wounds is carried out by the physician. Haemothorax or haempneumothorax persists in the majority and treatment is largely guided by radiological control. Until some two years ago the initial aspiration was delayed up to four days, and even this was considered to be setting the pace. Present opinion and experience indicate that early aspiration, even on the morning following operation, is advisable, and amounts of up to two pints (1.14 l.) of blood-stained exudate have been aspirated without undue distress. Air should always be aspirated first, for in some cases where this was delayed difficulty was experienced in obtaining complete re-expansion of the lung. Aspiration of fluid is then repeated daily or on alternate days until the chest is dry. After aspiration, 50,000 units of penicillin are introduced into the pleural cavity every two days. Absorption by the pleura is slow, and penicillin concentration is maintained at a relatively high level. It is stated by d'Abreu *et al.* (1944) that one to five units per ml. of fluid aspirated have been found up to four days after introduction. This concentration is considerably higher than that attained in the blood, which is about one-tenth of a unit per ml. after intramuscular injection of a similar dose. In addition penicillin is required in cases of multiple injury, to prevent pleural sepsis from wound contamination, and to control infection from foreign bodies lodged in the mediastinum. Breathing exercises carried out under supervision have proved of value in obtaining re-expansion of the lung and should be instituted as soon as the patient is able to co-operate.

The duration of stay of these patients in the C.C.S. is tending to increase. During the earlier phases of the campaign many cases of penetrating chest wounds were evacuated on the second post-operative day. They are now held up to five or six days or, better still, until the pleura is dry and dyspnoea at rest subsided. A marked improvement in their condition has been reported from base since this policy has been adopted. Duration of stay of thoraco-abdominal cases in the C.C.S. determined by the abdominal lesion. An interval of 10 to 14 days must elapse before these can begin the journey to base.

Mortality

Of the total of 220 patients (Table I) 7 were dead on admission and 18 were moribund or failed to respond to resuscitation. The operative mortality in the series of 100 cases under consideration was 16%.

TABLE III

	Pre-operative Deaths in 220 Cases Admitted to the C.C.S.			Post-operative Deaths in 100 Cases under Review	
	Total Cases	Brought in Dead	Failed to Resuscitate	Total Cases	Deaths
July ..	57	3	2	18	4
Aug. ..	45	—	5	18	3
Sept. ..	30	—	3	19	7
Oct. ..	63	2	6	26	1
Nov. ..	20	—	1	15	1
Dec. ..	5	—	1	4	—
Totals ..	220	7	18	100	16

Deaths following operation have been ascribed to several factors: (1) gross intrathoracic damage, 3 cases; (2) associated injury, 6 cases; (3) thoraco-abdominal injury, 5 cases; (4) blast-

lung, 2 cases. There was no definite evidence of injury to the pericardium, myocardium, great vessels, trachea, or oesophagus in the cases operated on in this series, but it is possible that a proportion of those who were brought in dead or failed to resuscitate died from such injuries or from thoraco-abdominal wounds.

Summary

A series of 100 cases of chest injury with a mortality of 16% is reviewed.

Chest injuries occurred in 6.6% of admissions to a casualty clearing station in active battle phases.

Early occlusion of the sucking chest wound is the most important first-aid measure.

Transfusion at field ambulance level is rarely advisable: pre-operative transfusion at the C.C.S. is required mainly on account of associated injury. The presence of a chest wound is no contra-indication to transfusion.

Arrest of haemorrhage, removal of devitalized tissues and accessible foreign bodies, and sound closure of the pleura should be the aims of forward surgery.

Intrapleural penicillin should be given to prevent sepsis in the lung and pleura. Penicillin should be injected intramuscularly for mediastinal or other associated injuries.

Early and repeated aspiration of air and fluid should be instituted and continued until the chest is dry and the lung expanded.

Causes of death are indicated.

Our thanks are due to Lieut.-Col. R. Evans, R.A.M.C., for permission to publish this article; to Brig. R. K. Debenham, Consulting Surgeon, Second Army, for helpful criticism; and to Lieut.-Col. G. A. H. Buttle and G. A. G. Mitchell, R.A.M.C.

MYELITIS FROM MUMPS

BY

REGINALD LIGHTWOOD, M.D., F.R.C.P.

Physician in Charge of Children's Department, St. Mary's Hospital;
Physician to Out-patients, Hospital for Sick Children,
Great Ormond Street

The use of the name "epidemic parotitis" for the condition more commonly known as mumps unduly narrows our conception of this disease. Although parotitis is usually present it must not be assumed that it is either primary or essential. There is no evidence that the infective process begins in the parotid glands, and certainly it may take a number of atypical forms, notably submaxillary involvement, orchitis, mastitis, and pancreatitis. Neurological syndromes must also be recognized and the commonest of them is a lymphocytic meningeal reaction which may be brisk enough to cause the classical signs of meningitis, although, more often, it is a minor symptomless change discovered only as a result of lumbar puncture. Close study of this meningeal reaction has suggested that the mump virus is primarily neurotropic (a view which Doptor holds). Thus, examination of the cerebrospinal fluid of symptom-free mumps contacts (Laverne *et al.*, 1938) showed an increase in the lymphocytes in many instances. Usually this increase was found three days before the end of the incubation period. The ordinary signs of mumps followed in some of these cases showing lymphocytosis, but not in all. This evidence suggests that the primary localization often occurs in the nervous system and that the contacts showing only the lymphocytic reaction had had abortive attacks.

Much less frequently the neurological manifestations of mumps are of a major order, taking the form of acute meningitis, encephalitis, myelitis, or a combination of the foregoing. A few instances of what appeared as neuritic lesions have also been recorded in mumps. It is said that the neurological symptoms appear most usually at the height of the attack of mumps, although they may precede or follow it by a few days.

Clinical involvement of the parotid glands not being an essential feature of mumps, the development of a neurological picture without parotitis may present a difficult problem in

diagnosis Harris and Bethell (1938) described a case of meningo-encephalitis and double orchitis, yet without parotitis, and Frankland (1941) in a mumps epidemic among soldiers saw some patients with meningeal involvement who had neither parotitis nor orchitis, and postulated that this epidemic may have been caused by a neurotropic type of virus. Similarly, a child with acute meningitis following contact with mumps was seen by me, the fluid was opalescent with lymphocytes and there was spontaneous recovery, neither parotitis nor any other sign of mumps supervening. Again, mumps parotitis may be so slight as to attract little or no attention. Halcrow and Wang (1945) described orchitis and meningo-encephalitis which came on three days after an almost latent parotitis. Thus an acute neurological syndrome accompanying parotitis or orchitis is not likely to cause difficulty, but in their absence the diagnosis may be difficult. The clinician will be helped if a history of contact is obtained and a knowledge of the possible neurological pictures will also be of assistance.

Mumps can lead to any of the following conditions: meningo-encephalitis, encephalomyelitis, labyrinthitis, optic neuritis, neurorhinitis and retrobulbar neuritis. Paralysis of a cranial nerve may be seen in mumps encephalitis, notably involvement of the seventh nerve (Ford, 1937). In writing of myelitis Ford mentions the possibility of paralysis of all four limbs, also of paralysis of the diaphragm, and cites two cases of the ascending type of myelitis similar to Landry's paralysis. He also quotes two cases of "local paralysis" recorded by Dopter and by Janbon *et al.* respectively. An example of the local type of paralysis, in which there was paralysis of the serratus magnus following parotitis and orchitis, is given by Harris and Bethell (1938).

When mumps attacks the nervous system the prognosis as a general rule is good and recovery may be expected within a few days, frequently, indeed, it is dramatic. There are two exceptions to this favourable prognostic rule: deafness provides one, and occasionally fulminating cases of meningo-encephalitis have proved to be fatal. Donohue (1941) recorded such a case, and the histological lesion was a perivascular demyelination similar to that seen in other cases of post-infective encephalitis.

The following example of "local paralysis" resulting from mumps is of interest, especially as it bore a strong resemblance to poliomyelitis. It is not possible to say for certain whether the causative lesion was a true myelitis or perhaps meningoradiculitis or neuritis, however, no sensory loss was found.

Case Report

A boy aged 16 years 9 months developed bilateral parotid mumps on March 28, 1945 and Dr. H. Gwynne Jones who saw him, found the temperature raised to 102° F., by March 31 it had subsided. However, with the appearance of orchitis on April 3 the fever returned (101° F.). Two days later (April 5) the boy noticed pain in his right knee and a numb or "dead" feeling in the leg and when his doctor visited him he found that he had to exclude the possibility of poliomyelitis. On examination that evening I noted the following: He was flushed, temperature 105° F., headache, which increased on standing up, patient not drowsy, tongue furred. The parotid swellings had subsided, but there was still orchitis on the left side. There were no other abnormal findings except in the nervous system: fundi and cranial nerves normal, no cervical or spinal rigidity, Kernig's sign positive, right knee jerk absent, right ankle jerk diminished, plantar reflexes flexor, weakness of the flexor muscles of the right calf and of the anterior tibial muscles of the right leg. There was no sensory loss. Lumbar puncture was not thought to be necessary. The temperature subsided during the next 48 hours and the patient recovered without sequelae except for a sensation of "pins and needles" in the right foot for about a week after getting up.

Summary

An example of mumps is presented, showing parotitis followed by orchitis and then myelitis which caused "local paralysis". Without this clear evidence of mumps the sudden development of paralysis of this type would almost certainly have been ascribed to poliomyelitis. Recovery set in early and proved to be complete.

INTESTINAL OBSTRUCTION DURING LATE PREGNANCY

BY

D. W. JAMES, M.B., B.S., D.Obstet.R.C.O.G.

Group Obstetrician, Hertfordshire County Council

Intestinal obstruction complicated by the existence of a viable child *in utero* presents the same problems that are common to all abdominal emergencies occurring late in pregnancy. The diagnosis is not easy, and the presence of the enlarged uterus renders operative treatment difficult. Lower-segment Caesarean section performed at the same time is a formidable undertaking, especially if intestinal resection is necessary. On the other hand, if the pregnancy is allowed to continue, a situation may arise in which the patient is subjected to a natural labour during the critical days which are likely to follow an operation of this kind. The following case illustrates another possible method of treatment. It is reported in order to show that in certain favourable circumstances laparotomy for intestinal obstruction may be delayed until natural delivery has been effected.

Case History

Mrs. A., aged 26, a 2-gravida, was admitted to the North Herts and South Beds. Hospital on Dec. 4, 1945, at the 32nd week of pregnancy, for acute abdominal pain and vomiting. In 1936 she had had an operation at which an ovarian cyst had been removed. In 1938 appendicectomy had been performed. In 1940, following recurring attacks of abdominal pain, she had been x-rayed after a barium meal, and had been told that she had a "twisted bowel." She was advised that an operation was unnecessary unless her symptoms became worse. In 1942 she became pregnant, and the attacks of abdominal pain were aggravated during this pregnancy. Delivery, however, was accomplished spontaneously at term after a quick and easy labour lasting 10 hours. After the birth of the first child she had no more attacks of abdominal pain until she became pregnant again. This time the attacks were worse, and it was one of these, associated with severe vomiting, that finally brought her to hospital.

On admission she complained of spasmodic pain in the upper abdomen and she had vomited several times during the day. Her temperature was 100° and her pulse rate 98. There was a small scar in the right iliac fossa, and a larger scar having the appearance of a Battle's incision which had been prolonged upwards. The size of the uterus corresponded with the dates, the foetal head was engaged in the L.O.A. position, and no obstetric abnormalities could be found to account for the abdominal pain. The epigastrium was distended and some peristalsis could be seen. A vaginal examination showed that the foetal head was low in the pelvic cavity and there was no dilatation of the cervix. No uterine contractions were felt. Her bowels had not acted for two days. Subacute intestinal obstruction was diagnosed, and a treacle enema produced a good result with some improvement in her general condition. The following day she complained of slight abdominal pain but did not vomit. Further enemata were returned clear, but she remained fairly comfortable all day. The next morning, however, she complained of increased pain and vomited about 1 pint (570 ml.) of dark fluid. Her pulse rate remained at 100, but the uterus was now contracting and it was difficult to distinguish intestinal colic from possible uterine pain. On vaginal examination the cervix appeared to be taken up, and as it was thought that she was about to start labour the membranes were ruptured artificially. Five hours later she was delivered spontaneously of a living child weighing 6 lb. (2.7 kg.).

Immediately after delivery she complained that she still had severe abdominal pain, and, with the uterus now well retracted, the signs of intestinal obstruction were obvious. The abdomen was very distended, and the thinness of the abdominal wall after delivery made the peristalsis in the distended coils of intestine plainly visible. There was also a point of tenderness over the larger of the two scars. An enema again failed to produce a result, and four hours after delivery her general condition had deteriorated and it was decided to perform laparotomy.

Operation.—The abdomen was opened through a right lower paramedian incision, and a quantity of dark blood stained fluid was found in the peritoneal cavity. The approach was rendered difficult by numerous adhesions between the omentum and the abdominal wall and by the distended coils of intestine. Inspection of the caecum was also difficult because it was bound down by adhesions in the right iliac fossa. It was found to be collapsed, and the peritoneal surfaces of the two scars were then inspected. A thickened band attached to the larger of the two scars was divided, but the coils of intestine remained distended. A further search revealed that the real site of the obstruction was at a point 3 in. (7.6 cm.)

above the ileocaecal junction, where angulation of the ileum had been caused by adhesions to an enlarged gland. After this portion of the ileum had been gently dissected free the obstruction was relieved and it was decided to do nothing further. The abdomen was closed without drainage. The uterus had been observed to be well retracted and it had in no way added to the difficulty of the operation. A continuous intravenous drip saline was given, and next day the patient was quite comfortable. A bile enema produced a faecal result with much flatus, and this was repeated twice daily for two days, after which the bowels acted naturally. There were no puerperal complications, and the child, although eight weeks premature, made good progress. Both were discharged from hospital after four weeks.

Commentary

The causes of intestinal obstruction during pregnancy are the same as those which produce it in the non-pregnant state. It is probable, however, that pregnancy predisposes to an attack. This is explained partly by the rearrangement of the viscera due to pressure by the enlarged uterus, and partly by the physiological atony which is believed to occur in the smooth muscle of the intestine as a result of endocrine changes.

From the obstetric point of view there are four possible methods of treatment, depending upon whether the obstruction is acute or subacute. They may be summarized as follows:

1. Immediate laparotomy. Lower-segment Caesarean section followed by treatment of the obstruction on general surgical principles.
2. Immediate laparotomy. Relief of the obstruction without disturbing the pregnancy. Morphine and progesterone to postpone labour as long as possible.
3. Surgical induction of labour. Spontaneous relief of the obstruction after delivery.
4. Surgical induction of labour. Laparotomy immediately after delivery if the obstruction is unrelieved.

The method chosen will depend upon the individual case. The first method is recommended by DeLee and Greenhill (1943) for all cases in which the symptoms are urgent and the child is viable. The second method would be chosen by most obstetricians only in the early months of pregnancy. The third and fourth methods are applicable only to certain cases of subacute obstruction, and may be considered together in connexion with the case described.

It has been shown experimentally (Wright, 1940) that animals with low and uncomplicated obstruction can be kept alive for as long as 28 days provided that sufficient fluid containing chloride is given and vomiting is controlled by aspiration of the stomach. Valuable time may thus be gained in cases of subacute obstruction. Moreover, uterine contractions are likely to be initiated by the violent peristalsis of the intestine, and conditions are therefore favourable for the onset of labour.

Before deciding to delay the laparotomy when the obstruction appears to be subacute, it is necessary to be absolutely satisfied on three conditions: (1) that strangulation is absent; (2) that obstruction is low; (3) that there is a reasonable prospect of rapid delivery. The first and second of these can be determined only by clinical observation. The third depends upon the history of previous labours, the state of the cervix, and the presence or absence of uterine contractions.

In the case recorded above all three conditions were favourable. The obstruction was at first subacute and uterine contractions were detected after 36 hours. After delivery the obstruction was not relieved, but the operation was made considerably easier by the absence of the enlarged uterus, and the patient was saved an unnecessary Caesarean section.

As a part of the health programme for displaced persons, two x-ray teams will visit U.N.R.R.A. displaced persons' centres in the U.S. zone of Germany. Each team consists of a doctor and three technicians from the International Red Cross, using mobile micro-film x-ray units carried in ambulances. This mass operation, to be completed in a reasonably short time, will enable U.N.R.R.A. to discover and treat incipient cases of tuberculosis as well as improve the methods used in the advanced cases. Its hospitals in the U.S. zone now have 2,000 beds for patients.

TRAUMATIC BLEPHAROSPASM AS AN ISOLATED SYMPTOM

BY

G. P. CROOKES, M.B., B.Ch., D.O., D.O.M.S.
(Oxford Eye Hospital)

The following case of spasm of the orbicularis oculi, which occurred as the result of trauma and responded to local nerve blockage with procaine, is described because no record of any similar occurrence is to be found in the literature.

Case Record

A girl aged 13 attended hospital with a history that her brother had poked a stick in her right eye five days previously, since when she had been unable to open it. On examination this eye was screwed up as though a foreign body were present. She was unable actively to open it, but it was easy to force the lids apart, revealing a normal globe. There was no conjunctivitis or any other inflammatory process, and no foreign body was present. The skin surface of the lids was intact and there was no bruising or oedema, but fibrillary twitchings of the orbicularis oculi were evident on inspection. This finding was magnified on palpation, when the muscle could be felt twitching beneath the fingers, giving the same impression as if a sparrow or other small bird were in the hand.

A diagnosis was made of spasm of the orbicularis. The treatment adopted was blockage of the facial nerve as in akinesia for cataract extraction. Two ml. of procaine was injected at the neck of the mandible with satisfactory results. Within five minutes the twitching ceased and the patient could open and close her eye in the normal way. Breakage of the vicious circle was all that was required, for when seen four days later there had been no recurrence and full movement of the lids was present. Vision was 6/6 in each eye.

Discussion

'Reflex blepharospasm occurring in conjunction with external lesions of the globe is an everyday incident; isolated blepharospasm unconnected with bulbar mischief is rare.' Benedict (1941) has usefully classified the condition as symptomatic, hysterical, and essential. The first of these, whilst reflex in origin, is assisted by voluntary contraction in many cases, and is difficult to overcome on attempted passive opening of the lids, as all know too well from experience.

The hysterical type persists during sleep and is characterized by incomplete closure of the lids, which show fibrillary twitchings; attempted opening of them is attended with increase of spasm, but the condition can be cured by persuasion. Essential blepharospasm, on the other hand, presents tonic and clonic forms, and is precipitated by a lesion in the central nervous system; it is alleged to follow encephalitis in some cases, and has been observed in the Parkinsonian state. In that case the lid movements are athetotic, resembling those of the fingers, but attempts at forcible opening meet with increased resistance. In the present case the lids were separated comparatively easily and without the superintention of extra spasm.

Taylor (1934) describes a case of local tetanus in which the only muscles involved were the masseter and ipsilateral orbicularis oculi. The wound of inoculation was a laceration of the scalp incurred while diving in sub-tropical waters 17 days previously. The ocular manifestation was a tonic spasm of the orbicularis which resulted in a marked narrowing of the prepebral fissure without complete closure of the lids. The case responded to antitetanic measures combined with a reopening of the healed scalp wound, which was then swabbed with neocarbolol.

In cases of blepharospasm associated with trauma the findings will vary greatly with the individual case. It may be noted, however, of recent injuries that a surprisingly small number of cases show any blepharospasm, closure of the eye being due, reactionarily, to oedema or haematoma. Children of course form an exception to this, a voluntary contraction often being superadded owing to nervousness. But, in adults, lid spasm is seen commonly in diseases affecting the anterior segment, including injuries of some standing when iritis has begun, but only rarely in the earlier stages when they first attend hospital. In many cases a lid oedema will have damped down the response; others a paresis of the muscle resulting directly from the trauma must be presumed; while there is, of course, that large group

which has incurred ocular damage without injury to the lids. The case described falls in none of the usual classifications, and is readily amenable to treatment.

Medical Memoranda

Obstructed Labour due to Sacral Tumour of Foetus

Tumours occurring at the caudal end of the foetus are rare enough to be of real interest when they are met with. Chaffin (*Surg. Gynec. Obstet.*, 1939, 69, 337), quoting Calbet and Fochier, states that sacrococcygeal tumours of the newborn may be expected to arise once in approximately 34,500 births. One-fifth of these infants are stillborn. Others, although born alive, do not survive many days.

All types of tissue have been found in these tumours, from simple undifferentiated cells to a parasitic foetus. It occurs more frequently in females than in males. Commonly an antenatal diagnosis of a foetal abnormality can be made, but it is more often impossible till labour is well advanced, as in the case described below. If for no obvious reason labour is not proceeding according to plan, the existence of a tumour of the foetus causing delay would, of course, be thought of.

CASE REPORT

On April 28, 1945, Mrs. K., aged 41, was admitted to the County Hospital at 8 a.m. Her last child is now 12 years old. She had no obstetrical history in the meantime. On admission she was suffering from severe pre-eclamptic toxæmia. She was about two weeks off full term. Her B.P. was 185/110; albuminuria $++$; there was extensive oedema right up to the xiphisternum. It was not possible to diagnose the presentation by palpation, but the foetal heart was thought to be heard about half-way between the umbilicus and the pubis. A skiagram of the abdomen showed a single foetus lying in the longitudinal axis with the head fully extended into a face presentation.

She went into labour the same day about noon and progressed rapidly—so much so that the face, chin anterior, was lying on the perineum at about 1.30 p.m. There was no advance from this point even though conditions seemed favourable for a natural delivery. Forceps were applied, the head was delivered easily, and the anterior and posterior shoulders were extracted. From here the foetus would not budge even with a strong pull in both foetal axillæ. A hand was inserted beyond the foetus and a large soft cystic lump was found attached to the foetal buttocks. It felt larger than a foetal head. A long wire was passed into the uterus under guidance of the already inserted left hand and a hole made in the tumour. Thin blood-stained fluid came away. The tumour was now broken up to reduce its size. The child was then extracted, and in so doing the tumour separated from the foetus and was left behind in the uterus. It was easily delivered manually afterwards.

The foetus was a well-developed female stillborn infant weighing 5 lb. 12 oz. (2.6 kg.). The area from which the tumour arose extended over the whole buttocks. The lower end of the sacrum and coccyx was absent. The lower end of the gastro-intestinal tract was long and tapering, ending apparently in the perineal end of the tumour mass. The anus was imperforate. There was no other foetal abnormality.

Description of Tumour.—It weighed approximately 3 lb. 1 oz. (1.39 kg.). It was a large soft cystic mass covered with healthy skin and no hairs. On the perineal end of the skin there was a small dimple to which the imperforate intestine was attached. Throughout the mass were groups of cysts filled with blood-stained light fluid, and in other areas were soft gelloid masses looking not unlike a sarcoma. Microscopic appearance: "The tissue consisted of an embryonic matrix resembling glial tissue, in which were acini lined with epithelium, columnar in type with a suggestion of ciliation. The outstanding feature was masses of hyaline cartilage. The tumour is a congenital sacral teratoma."

The mother made an uninterrupted recovery. Her blood pressure was normal and the albuminuria had disappeared within two weeks.

I wish to thank Prof. W. D. O'Kelly for the pathological report.

JOHN J. WALLS,
M.D., M.R.C.P.I., D.P.H.

County Hospital, Roscommon.

The National Council for the Unmarried Mother and her Child held in London last November a conference entitled "Homes and Hostels of the Future," when the speakers included Dr. Dorothy Taylor, Dr. John Fenton, M.O.H. for Eastbourne, and Dr. Letitia Fairfield. The conference was attended by a very representative audience of over 350 people. A full report has now been printed as a pamphlet of 48 pages, and copies are available at 1s. 6d. from the general secretary, N.C.U.M.C., Carnegie House, 117, Piccadilly, London, W.1.

Reviews

SURGERY OF THE HAND

Chirurgie de la Main. By Marc Iselin. (Pp. 238; illustrated. 145 francs.) Paris: Masson et Cie.

This volume is a study of the treatment of injuries of the hand of every type and is evidently based upon a very wide experience. The opening chapters deal with the examination of the injured hand in order to ascertain the precise nature of the injury, which is often so different from what at first appears, and this is followed by a brief account of the methods of treatment and the general results of injury, including the fixation of joints and tendons. Now comes an admirable account of the treatment of cutaneous lesions, which in the hand may be of supreme importance, and this includes detailed descriptions of methods of grafting and of the treatment of burns and contracted scars. There follows a discussion of the modern methods of treating divided tendons, and only those who have dealt with these difficult cases can appreciate the importance of these methods. The next section is on nerve injuries, and here we must part company with the author as regards the treatment of the nerves themselves, though there are valuable suggestions for the management of the damaged hand. The later chapters describe ingenious methods for replacing lost fingers, and especially the reconstruction of the thumb, and deal with prosthetic appliances for use after amputation.

With the one exception of the chapter on nerve injuries, which after all is a very special subject, the book is admirable and contains many ingenious proposals and suggestions of value. The importance of injuries of the hand is fully recognized today, and we regard this as a valuable contribution to the subject.

SULPHONAMIDE TREATMENT

The Sulphonamides in Theory and Practice. By J. Stewart Lawrence, M.D., M.R.C.P. (Pp. 125. 9s.) London: H. K. Lewis and Co. 1945.

Dr. J. Stewart Lawrence in *The Sulphonamides in Theory and Practice* has produced what we believe to be the first British book on this subject, although M.R.C. War Memorandum No. 10 has served the same purpose, despite its unbound condition and modest price. This book is of modest size, and gives a simple account of sulphonamide therapeutics, after describing the properties of the various drugs and dealing briefly with their *in vitro* study, particularly from the point of view of relative degrees of activity. An interesting feature is provided by the author's original observations on the treatment of six conditions, each represented by a series of cases with controls. Sulphonamide treatment was of no apparent benefit in tonsillitis, influenza, or bronchitis; there was, of course, marked benefit in urinary tract infections. Sonne dysentery responded best to sulphapyridine, and the same drug, administered for several months, is somewhat surprisingly effective to have been of benefit in pulmonary tuberculosis; the effect is believed to have been on the tubercle bacillus itself, since it is categorically stated that "the secondary invaders were quite unaffected." Penicillin is not mentioned except in a brief final chapter on the relative indications for these two forms of chemotherapy. The author suggests that in infections due to organisms susceptible to both, the indications for penicillin are suppuration, necrosis, or bacteraemia. This is an ingenious rule, but not to be taken too literally or in disregard of other factors in the individual case.

This book should be of considerable service to the practitioner: if its precepts were generally followed sulphonamide therapeutics would be more efficient, and the consumption of these drugs would probably diminish by half.

A TEXTBOOK OF MEDICINE

Textbook of Medicine. By various authors. Edited by J. J. Conybeare, M.D., F.R.C.P. Seventh edition. (Pp. 1,164; illustrated. 30s., plus 9d. postage.) Edinburgh: E. and S. Livingstone. 1945.

It is a striking commentary on wartime developments that Dr. J. J. Conybeare's *Textbook of Medicine* in its seventh edition should be the fourth since 1939, and that more copies have been sold during the war than in the preceding ten years. Dr. Conybeare manages his team of sixteen contributors with

great skill, putting in his own work just at the right place, and the revisions for this edition indicate editorship at its best. Several pages on sulphonamides and half a page on penicillin, at the beginning of the section on infectious diseases, give an excellent summary of present-day chemotherapy and cleverly get over the difficulty that arises when advances come at a quicker rate than books can be printed and published. Sampling the text for advances in medicine reveals no serious deficiencies, though an unfortunate page reference (255 for 225) makes the finding of work on the rhesus factor a little difficult. Glandular fever now appears under infectious diseases; so does tetanus, though poliomyelitis is still in the section on diseases of the nervous system. These are problems that must haunt every writer or editor of a medical textbook, and it is, perhaps, unfair to mention them instead of stressing the sterling qualities of this work. But it has already won a firm place with students and practitioners, and as it seems likely to go on appearing in peace or war a word or two of criticism will not be taken amiss.

SURGICAL ANATOMY

A Manual of Surgical Anatomy. By Tom Jones and W. C. Shepard. (Pp. 195; 267 illustrations, 153 in colour. 25s.) London: W. B. Saunders. 1945.

There can be no doubt about the thoroughness with which the United States entered into all aspects of the prosecution of the war. Few in this country, for instance, would have thought that the preparation and publication of a book on surgical anatomy could be considered part of the war effort, yet that is the intention of *A Manual of Surgical Anatomy*. The fact that this was possible may be considered as an indication of the difference in the impact of the war on the two countries. The book was prepared under the auspices of the Committee on Surgery of the Division of Medical Sciences of the National Research Council especially "to furnish the Medical Departments of the United States Army and Navy with compact presentations of necessary information in the field of military surgery." The original manual was published just before the end of World War I, but the present volume (coming too late for World War II) is almost completely new.

The book is actually an atlas of some 267 anatomical drawings, with an explanatory index (giving both Standard English and B.N.D. terms) at the end. The line illustrations are all delightfully drawn by the two artist editors, whose styles are so similar that it is difficult on cursory examination to distinguish between them. In addition to the purely anatomical drawings there are others devoted to the illustration of applied anatomy, such as incisions, the technique of paravertebral injections, and so on. Those showing the operative exposures for various sympathectomies and in pneumonectomy are particularly well conceived and useful. On a page size of 11 by 8 inches (28 by 20 cm.) there is no need to cramp the drawings; in consequence a lot of detail which would otherwise be lost can be included.

Altogether an admirable volume, and at 25s. must in these times be acknowledged a bargain. The publishers also issue a pocket edition at 15s.

MEDICAL SCIENCE IN THE NETHERLANDS INDIES

Science and Scientists in the Netherlands Indies. Edited by Pieter Honig, Ph.D., and Frans Verdoorn, Ph.D. (Pp. 491; illustrated. \$4.00 or £1 1s.) New York: Board for the Netherlands Indies, Surinam, and Curaçao; London: William Dawson and Sons, Ltd. 1945.

For many years before the war of 1939-45 the Dutch Government medical staff in Java issued—year by year—pamphlets recounting their researches. These disappeared during the military occupation, and the material is now dealt with in the volume *Science and Scientists in the Netherlands Indies*, which gives a picture of the development and status of a number of branches of the natural sciences in Indonesia. The present work consists of original articles, biological sketches, reviews, and a list of scientific institutions.

Formerly there were three services in Indonesia—the civil medical, the military medical, and the vaccination service. More recently a public health service was instituted to provide curative medicine for the inhabitants of the archipelago. This now gives special attention to prevention of disease. There are medical colleges, central and regional laboratories, institutions for leprosy and smallpox—all of good standard; also a number

of medical journals, published weekly. In this large tropical belt (an area of 760,000 square miles, 3,000 islands, and 65,000,000 inhabitants) there is wide scope for investigation and research. Malaria is rife and much attention is paid to the control of it. The numerous salt-water lagoons have been found to be ideal for *Anopheles sundaicus*, which, though not a carrier of malaria in other parts of the world, is one of the most dangerous vectors in the Netherlands Indies. Since 1921, thanks to careful quarantine measures and extensive vaccination, the archipelago has been almost free from cholera. Though nearly all the epidemics were due to genuine cholera vibrios, strains isolated in the Celebes Islands were found to be definitely haemolytic. The aetiology of a group of febrile diseases was traced to a spirochaete, closely related to the leptospirae which cause Weil's disease. Plague, which first reached Java from Rangoon in 1905, has since become endemic. In 1933 there were over 20,000 cases, but since 1939 plague diminished considerably. Its incidence in the ports and on the coasts of Java has always been negligible.

This book is full of interesting data on diverse tropical subjects, though one might hope that subsequent issues will be less bulky and not so heavy. The many good illustrations give a clear idea of the country and its scientific institutions.

Notes on Books

Dr. Maitland Radford's last appointment was that of M.O.H. for St. Pancras, the borough in which B.M.A. House stands, and he became well known to many members visiting headquarters or working here. His death in 1944 was widely and deeply mourned. All could recognize his brilliant gifts, but not many were aware that he wrote occasional verse. Some of his friends, headed by Dr. C. E. Wheeler, have prepared a small volume *Poems by Maitland Radford*. These twenty-eight short pieces reflect vividly the man they loved. Dr. Wheeler's introduction is followed by contributions headed "Maitland as we Knew Him" by seven intimates, and a preface to the poems by Sir Henry Slesser. During the thirty years covered by the poems in this volume Maitland Radford did not write one line he had been specially stirred by some incident of his experience emotional or intellectual, or both. The edition—a fine example of book production—is limited to 500 copies, and George Allen and Unwin Ltd. are the publishers (price 7s 6d.).

H. K. Lewis and Co. have published a second version of the little book entitled *Notable Names in Medicine and Surgery*, by M. HAMILTON BAILEY, F.R.C.S., and Mr. W. J. BISHOP, Sub-librarian of the Royal Society of Medicine, which was noticed in these columns after its first appearance in 1944. There is no need now to do more than quote the subtitle, "Short biographies of some of those whose discoveries (not necessarily the greatest medical discoveries) have become eponymous in the medical and allied professions." The price is 15s.

The British Drama, by JAMES BRIDIE, is No. 12 of the pamphlet published at 1s. 3d., under the general heading "The British Way" by Craig and Wilson Ltd., 70, Bath Street, Glasgow. One or two earlier members of the series have had health and science as the subjects. Our reasons for mentioning this one are that the author (Dr. O. H. Mavor to us) is physician as well as playwright; that anything Bridie says is always worth listening to; and that doctors are not indifferent to the art of the theatre, about which he writes with knowledge, cool common sense, and pungency.

MISS EVELYN PEARCE, for many years senior sister-tutor at Middlesex Hospital, has added to her writings for the benefit of nurses a booklet *First Aid Quiz*, reprinted from the *Nursing Mirror*. It is published at 3s. 6d. by Faber and Faber.

Hospital Care of the Surgical Patient, by Drs. GEORGE CRUJN, and FRANKLIN L. SHIVELY, jun., was reviewed in this column, Aug. 26, 1944, when we said that a newly appointed house officer would find it of considerable value in his early encounters with surgical patients. A second edition has now been received from Charles C. Thomas, 301, East Lawrence Avenue, Springfield, Illinois, U.S.A., price \$3.50; it is published in this country at 14s. Baillière, Tindall and Cox.

The Joint Tuberculosis Council has issued two pamphlets which were approved on Nov. 17, 1945. One is the second report of the Committee on Development of the Tuberculosis Services (formerly the Committee on Reorganization of the Tuberculosis Service) and the other is a memorandum of advice on Mantoux conversion in hospital and institutional staffs. Copies may be had from the honorary secretary, Joint Tuberculosis Council, 1, Becket Street, Oxford.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MARCH 30 1946

THE HEALTH SERVICE BILL

The National Health Service Bill was published on Thursday last week. The White Paper summarizing its provisions is printed in the opening pages of this week's *Journal*, along with a statement on it issued by the British Medical Association. The Association has already circulated both these documents to all members of the profession. The second reading is expected before Easter, and the Government is likely to hasten on legislation. Medical men will therefore have to think clearly and quickly if they are to secure those modifications in the Bill which they believe will ensure the progressive evolution of the science and art of medicine. Anything which hinders or hampers this will harm the public.

Medical thought has always found its fullest expression and originality in an atmosphere of freedom. It has become stagnant and retrogressive when it has been restricted by external authority. For long periods in the past Medicine has been kept immature by the dogmas of those in power. In the worship of the State, which is the modern dogma, it is threatened by forces no less powerful than those of the past. If Medicine is to extend its frontiers and renew its strength in each generation it has to go on working out its own salvation and keep itself clear from the influence of prevailing ideologies founded on less exact knowledge. This is what "freedom of the profession" means. The Anglo-Saxon world has made its great contributions to medical knowledge in the framework of a free tradition which makes the highest call on individual responsibility and initiative. It is now our collective responsibility to the future to see that this framework is not destroyed and replaced by a prefabricated structure, however dazzlingly bright the new gadgets may appear to the designer's eye. We must hold fast to what has been proved good and see that it continues. If the new service in its evolution can preserve the continuity of what is sane and sound in our medical history the details will fall into place; adjustment of these is a matter of ingenuity; but if the structure is unsound no amount of ingenuity will improve it—if it is rigid it will crack at the first strain.

In brief, the Bill offers to the whole of the population of Great Britain a complete medical service—general practitioner, consultant and specialist, institutional, nursing—free of immediate charge for the service rendered. It excludes the industrial and the school medical services and therefore is not comprehensive. The cost of the service will be paid for by the ratepayer, the taxpayer, and the contributor to the national insurance fund. The "middle-men" who distribute the public's money to the doctor and the hospital

and the health centre will be the Minister of Health, the Regional Authority, and the Local Authority. The pooling and distribution of money in some such way as this is necessary if a nation-wide organization, for example, of hospitals, is to be efficient. To what point it should be carried in the provision of personal services needs consideration.

The Minister of Health is to have responsibility for the service, and considerable powers in the exercising of it. The principal feature of central organization is the Central Health Services Council, composed of representatives of the main operatives in the service—doctors, dentists, nurses, midwives, chemists, and hospital and local government managers. Medical representatives will be in a majority. The function of the Council will be advisory, not executive. There will also be standing advisory committees on special aspects of the service, and these are to be empowered to advise the Minister directly. A small Central Committee on the Distribution of Medical Practices, mainly professional in composition and working under the direction of the Minister, will supervise the distribution of doctors in the service. This Central Committee will decide whether a doctor may start a new practice or change from one to another in the public service.

Local administration will be effected through (1) Regional Hospital Boards and Local Hospital Management Committees; (2) County and County Borough Councils for certain domiciliary and clinic services; and (3) Local Executive Councils for family practitioner services by doctor and dentist. The Minister of Health proposes to become the owner of all the hospitals in the country, voluntary and municipal, special and general, teaching and non-teaching. He proposes, in fact, to rope all hospitals into a State Hospital Service. A consultant service will be based on the hospitals.

The endowments of voluntary teaching hospitals will pass directly to the new Boards of Governors. A Hospital Endowment Fund will absorb the endowments of other voluntary hospitals. After existing debts and liabilities have been met from this the Minister will then apportion the capital value of the Fund among the Regional Hospital Boards.

Regional Hospital Boards—to the number of 16 or 20—will administer all hospitals in "natural hospital areas" based on the eleven University medical teaching centres in England and Wales. The Minister will appoint the members of these Boards after consulting the appropriate university teaching centre, the medical profession, and the local health authorities. Within the Region, Local Hospital Management Committees appointed by the Board will be responsible for local groups of hospitals, or for single large hospitals. These committees will be made up of representatives of local authorities; general practitioners in the area, and senior medical and surgical staff of the hospitals concerned. Undergraduate and postgraduate teaching hospitals will be managed by their own specially constituted Boards of Governors, with representation of the university and teaching staff. They will also have members nominated by the Regional Hospital Board and members appointed after consultation with the major local

authorities concerned. The teaching hospitals will have separate financial arrangements. The Governors, advised by a selection committee, will appoint their own staff. Private patients may be treated in separate hospital accommodation by part-time specialists in the service, provided that fees are within a controlled scale and that non-paying patients may be treated in the same accommodation if medical considerations require this.

The second part of the proposed local organization concerns certain clinic and non-hospital services the administration of which becomes a statutory duty of the Local Health Authorities—County Councils, County Borough Councils, or combinations of them. The services include maternity and child welfare; domiciliary midwifery; health visiting; home nursing; vaccination and immunization; ambulances; provision of Health Centres; and the school medical service (under the Education Act, 1944).

General practice will be conducted from Health Centres provided and equipped by the Local Health Authorities or by arrangements with doctors in separate practice who will join the service from their own surgeries. Local Executive Councils (successors in effect to the Insurance Committees)—one for each local health authority—will arrange for the general practitioner services in accordance with regulations under the Act; make contracts with and remunerate the doctors, dentists, and chemists in the service; provide local disciplinary machinery; and make available information on the facilities of the service. The Local Health Authorities, as mentioned, will provide, maintain, and equip Health Centres, and appoint nursing, secretarial, and other auxiliary staff to them. The local authority will arrange with the Local Executive Council for the use of the centres by the doctors and dentists in contract with it. General practitioners in the service will receive a basic salary plus a capitation payment which tapers as the number of persons on the doctor's list increases. The Government proposes to abolish the sale and purchase of public practices and to pay compensation on terms announced elsewhere in this issue. Finally, a National Public Laboratory Service for the control of infectious diseases has been set up through the agency of the Medical Research Council.

Such in brief outline is the scheme now before Parliament, the public, and the profession. The Council of the A. is "opposed, on grounds of public interest, to . . . in important features of the Government's proposals," and the reasons for this opposition are set out clearly on pages 469-74 of this week's *Journal*. The Minister is proposing to set up at least three services—a hospital service administered regionally; a general practitioner service administered by one form of local organization; and clinic services administered by another form of local organization. Add to this a school medical service administered under the Education Act, an Industrial Medical Service run partly by industry and partly by the Ministry of Labour, the existing Public Health Service shorn of its major attractions, and two forms of laboratory service (National and Local)—and it seems as if the Minister has failed to co-ordinate the whole into a "comprehensive" health service. The B.M.A. Council proposes as a rational step that co-

ordination should be effected at the regional level. The Regional Boards, it suggests, should own and administer Health Centres. The Boards should, in fact, be responsible for all treatment as distinct from environmental services. As to central organization, the B.M.A. Council would like to see the Central Health Services Council made a working instrument by having the reports of the standing committees submitted to it, and by it to the Minister.

Although it does not own the voluntary hospitals of this country, the medical profession is vitally concerned in their fate, because it is by, with, and from them that British doctors have for centuries received their nourishment and inspiration, especially the great teaching hospitals, and such intellectual pioneers as the Hospital for Nervous Disease in Queen Square and the Brompton Hospital in London. These institutions, and others like them, have more than a local habitation and a name. Their renown is world-wide. Whatever safeguarding clauses may be introduced, no one can regard with equanimity the proposal that these places of learning should become State hospitals owned by the Minister of Health. Is this proposed ownership put forward on medical or on political grounds? And if the Minister owns all the hospitals in the country, appoints the governing bodies, and appoints the Regional Boards and through them the Local Hospital Management Committees, what finally will be the status of the men who work in the hospitals? Outside the teaching hospitals they will be appointed by the Regional Boards. Will they not in the slowness of time become the employees of the solitary owner presiding over the Ministry of Health in Whitehall? It is the first blow that counts, and once the blow of ownership is delivered it would be surprising if it were not followed by others, delivered at the principle of private and personal responsibility for the conduct of professional life and action. Power whets the appetite for more power. The more responsibility is centralized, the less is the responsibility left to the individual. And the practice of medicine demands the highest exercise of individual responsibility. A committee can't heal a sick man.

The general practitioner of the future will work in a Health Centre owned by the local health authority and be paid, to begin with, partly by salary. He will be unable to start practice or change practice except by permission of a central committee working under the direction of the Minister at the Ministry of Health. Owning nothing except the right to work under direction—presumably not even the tools of his craft—and inspired by the prospect of controlled security, what kind of effort will the future general practitioner put forth? Will the kind of regimented medical service contemplated give the right setting and stimulus to the Jenners, Hunters, Budds, Snows, and James Mackenzies of the future?

To bring these questions into relation with Principle I of those listed on page 468 do the Government's proposals of State ownership of hospitals and local authority ownership of Health Centres—the two places of practice of the consultant and specialist and of the general practitioner respectively—lead "directly or indirectly to the profession as a whole becoming full-time salaried servants of the State or local authorities"? This is the question. If the answer

is Yes, then the medical profession must decide anew whether this is what it wants or does not want. If it decides that a State service would lead to the frustration of Medicine, then it would be against the interests of the public to promote it.

Once the dividing line is passed and doctors are absorbed in a service which in effect makes them all employees of central and local government their independence and professional freedom will come to an end. They will become officers in a technical service responsible to central and local officials. They will no longer have that direct responsibility to the patient which has hitherto been the inspiration of medicine and the mainspring of medical knowledge and ethics. Once all that is sound and sane in the tradition of Medicine is sacrificed to administrative convenience and centralized governmental control, then medicine will cease to be a profession. The Bill as a whole must be looked at in this light, and this must not be obscured by preoccupation with details. If the conception of the whole is right, and the framework such as will maintain the essence of professional tradition, then details can be adjusted. And it is for the medical profession as a whole to decide what the issue is to be.

REFECTION

Nearly 35 years ago, in a paper now recognized as one of the classics of modern nutrition, Hopkins¹ described the remarkable effects on the growth of rats of small additions of milk to a diet otherwise lacking in accessory food factors. Some years later the two great Americans, Osborne and Mendel,^{2,3} confirmed these findings, though they had to feed much more milk to get their rats to grow satisfactorily. Workers since have inclined to agree that milk in quantities as small as those used by Hopkins would not support growth, but the reasons for this discrepancy have remained unexplained for many years. The mystery has now been largely solved, and it is fitting that the solution should be given by Sir Frederick himself.⁴ It is gratifying to know that the distinguished doyen of biochemistry is still actively contributing to a science he helped so much to create. The explanation of the mystery lies apparently in the nature of the carbohydrate forming part of the purified ration. With rice starch, dextrinized potato starch, or sugar the amounts of milk originally used by Hopkins prove insufficient, but when the diet contains raw potato starch the old findings are confirmed in every detail. Though this was not specifically stated in the 1912 paper, it is clear from the recent publication that potato starch was used in the early experiments. Peculiar effects of this starch were noticed also by other workers. Fifty years ago Eijkman⁵ showed that hens given this carbohydrate instead of polished rice did not develop polyneuritis, while between 1923 and 1927 Randoïn and her collaborators published a series of papers⁶ describing its vitamin-sparing effects. They also

pointed out its low digestibility—a property previously noticed by Langworthy and Deuel.⁷

In the meantime a striking dietary phenomenon, which later was to prove especially closely connected with potato starch, appeared accidentally in the laboratory of Fridericia in Denmark in 1925.^{8,9} A young rat declining in the usual way on a diet containing raw rice starch and deficient in vitamin B suddenly recovered, started to grow, and at the same time began passing bulky faeces containing undigested starch. The condition could be transmitted to other deficient rats in that laboratory. This ability to grow and thrive in the absence of vitamin B from the diet was aptly called "refection" by Fridericia.⁸ By a curious coincidence it appeared somewhat later independently and spontaneously at the Lister Institute, also among rats receiving rice starch.¹⁰ About the same time Kon and Watchorn,¹¹ in studying the vitamin-sparing effect of potato starch, showed that with it refection, which with rice starch is an exceedingly rare spontaneous phenomenon, was of quite common occurrence. Their experience was abundantly confirmed by other workers.¹²

It is generally agreed that a "refected animal" is able to make use of the vitamin factors synthesized by its intestinal flora, though a normal rat may possess this faculty only to a small degree or even hardly at all. Attempts to explain the phenomenon in a simple way—for example, as an infection by a specific organism—have not been successful, and it appears that the condition is due to a fairly complicated chain of events. Hopkins and Leader⁴ favour the following explanation put forward by Kon *et al.*¹² Micro-organisms in the caecum thrive on the undigested starch present there, while the presence of starch-splitters leads to a vigorous fermentation, resulting in an acid pH. These conditions favour the synthesis of much larger quantities of vitamins of the B group than are formed in the alkaline caecum of a deficient rat in the absence of available carbohydrate. The acid reaction in the caecum enables the rat to absorb and utilize a proportion of the vitamins found there, and the animal becomes in fact akin to the ruminant in nutritional independence, the caecum acting as a vicarious rumen. The same reasoning can doubtless explain established rice-starch refection, but it has never been satisfactorily shown why the rat becoming spontaneously refected on a rice-starch diet suddenly and largely loses the power to digest the starch. There may possibly be some connexion with the rather similar condition of starch dyspepsia described in man by Hurst and Knott.¹³ The bacterial basis of potato-starch refection is well demonstrated by the inhibitory effect of sulphonamide drugs on the growth of refected rats¹⁴ and on the formation in their gut of vitamin B₁ and riboflavin,¹⁵ and the study of this interesting condition may well help in the investigation, on the one hand, of processes of vitamin synthesis and uptake in the ruminant, and, on the other, of the nutritional role of the symbiotic flora of man. It should

be noted, however, that some of the potato-starch effects may not be related to bacterial activity, and, indeed, Hopkins and Leader⁴ believe that the milk-sparing effect, in spite of superficial similarity, is different from, and wholly independent of, refection; and they do not exclude the possibility of the presence of certain growth factors in potato starch.

STREPTOMYCIN

We referred recently (Feb. 23, p. 278) to the use of streptomycin for the chemotherapy of tuberculosis. There are numerous other infections—notably those due to various Gram-negative bacilli—which may prove amenable to this substance, and the growing volume of American literature dealing with it is a measure of the hopes entertained for its future. Of all the innumerable antibiotics studied during the past few years streptomycin appears to be the only one combining a wider range of antibacterial activity than that of penicillin with such freedom from toxicity that parenteral injections of large doses are harmless. Discovered two years ago by Waksman and his colleagues, it is extracted from cultures of *Actinomyces griseus*, and has been obtained and used clinically in varying degrees of purity. Weight for weight it appears to be less active than penicillin, and the unit of activity is also even smaller: it is defined as that quantity which when dissolved in 1 ml. of broth will just prevent the growth of a standard strain of *Bact. coli*. A unit of penicillin so defined, with *Staph. aureus* as the test organism, would be roughly one-fiftieth of what it is, and the existing unit has been condemned as inconveniently small; why that of streptomycin has been so fixed that an ordinary daily dose runs well into seven figures is not clear.

Several groups of workers¹⁻⁴ have studied streptomycin pharmacologically. When given by the mouth it is scarcely absorbed at all, but retains activity and appears in high concentration in the faeces. For systemic effect it can be given subcutaneously, intramuscularly, or intravenously; it is then excreted by the kidneys, but more slowly than penicillin, with the result that injections at intervals of six hours suffice to maintain a therapeutic blood level. Like penicillin it must be given intrathecally in order to produce a therapeutic level in the cerebrospinal fluid, but it passes from the blood into other body fluids. No serious toxic effects have been seen, but injections into tissues may be painful and into veins may cause thrombosis; fever, uraemia, and headache have also been observed. To what extent impurities are responsible for such effects is not clear.

Streptomycin has naturally been exploited chiefly in infections due to bacteria insusceptible to penicillin. One of the earliest reports—that of Reimann *et al.*⁵—described the treatment of 5 cases of typhoid fever: these occurred in a single epidemic with unusual features, including an exceptionally prolonged course; treatment was started in some of the cases at a late stage, and the strain of *Bact. typhosum* was less susceptible *in vitro* to streptomycin than most. Even allowing for these unfavourable features, the results were not decidedly encouraging. The same may be said of the two cases of septicaemia due to Gram-negative bacilli described by Anderson and Jewell.⁶ On

the other hand they appear to have cured a patient with *H. influenzae* meningitis. Three cases of this condition, all treated with good results, are included in the series of 45 cases of various infections treated with streptomycin at the Mayo Clinic, and described by W. E. Herrell and D. R. Nichols.⁷ These infections include coliform septicaemias, chiefly associated with severe urinary tract infection, and simple urinary infections, in most of which results were good; several cases of undulant fever, in only one of which a really striking effect was obtained; and 5 cases of bronchiectasis treated by inhalation as well as intramuscular injection with 4 successes. *Bact. friedländeri* was eliminated from the sputum of 2 of these patients, and ozaena due to this organism seems also to have responded to some extent. The treatment of syphilis in 4 patients was followed by relapse. While the efficacy of streptomycin in some of these and other conditions mentioned cannot yet be assessed, there seems to be no doubt of its striking all-round efficacy as a urinary antiseptic. H. F. Helmholz⁸ has shown that *in vitro* all five species of bacteria commonly found in urinary tract infections are suppressed by a concentration only one-fifth of that attained in the urine by ordinary systemic dosage. No other drug has so all-embracing an action.

Streptomycin is still not generally available in the U.S.A. It is being supplied there to one or two hospitals, and is also being used for the treatment of men in the Forces injured in the war. When manufacture is well under way in the States we may expect supplies over here.

SMALLPOX IN THE VACCINATED

"The common tendency is both to underestimate and to exaggerate the capacity of vaccination to protect against smallpox." Because, within limits, that capacity is incapable of exaggeration it is not always realized that sometime the limits may be narrow and the duration of absolute immunity be short-lived. The purpose of vaccination being to confer protection against smallpox, it follows that any attempt at inoculation which fails to raise the level of immunity should be regarded as unsuccessful. Evidence of the immunizing properties of reputable vaccine-lymph is too firmly established to be shaken by a number of reports in the last few years, of smallpox in the recently vaccinated: these do, however, unfortunately leave no doubt that insusceptibility is sometimes assumed on insufficient grounds.

The course of events following primary vaccination is plain enough. In the interpretation of the results of re-vaccination the difficulties and the dangers lie. The immediate reaction can be seen in immunes and non-immune alike. The only certain valid evidence of (temporary) success is vesicle formation; and an assumption of the presence of complete insusceptibility made on the strength of almost any lesser grade of reaction involves a risk which grows greater as the interval since the last successful inoculation lengthens.

The severity of an attack of smallpox measures the resultant of two opposing forces—the patient's immunity and the virulence of the infective agent. The clinical features of variola major in the vaccinated are determined largely, though not wholly—by the level of the patient's acquired immunity at the time of his exposure to infection; and the most highly modified cases—which are prone to occur when often least expected, among individuals assumed to be vaccinated—are as likely to be diagnosed only in retrospect as are the most virulent toxic cases which form the opposite clinical extreme. Yet recent experiences have reminded

of the infectivity of the patient who bears but minimal skin blemishes. To him it matters little that his disease is small-pox; it may cost the lives of his unprotected contacts. The effect on this problem of the proposed repeal of the Vaccination Acts, 1867 to 1907, remains to be seen. Repeal of these Acts was recommended by the British Medical Association's Committee on Immunization¹ in 1935, and this recommendation was reaffirmed by the Council of the Association at its meeting in June of last year.

IDIOPATHIC FRACTURE OF THE FIRST RIB

As long ago as 1885 Arbuthnot Lane² suggested that fractures of the first rib were more common than was usually thought; but in 1937 Breslin³ found only 27 cases in a review of the literature, to which he added 5 of his own; Aitken and Lincoln⁴ described another case in 1939. Mass radiology surveys, however, are beginning to reveal that this fracture is not uncommon. The break is always situated just proximal to the scalene tubercle, and the skiagrams usually show an irregular fracture surrounded by a fusiform swelling of callus or solid bone. Alderson⁵ found 64 cases among 81,682 members of the Royal Navy. Of the 35 men in the first group which he reported 30 were under the age of 25. Only 11 in the whole series gave a history of symptoms of possible trauma, 2 complained of sudden pain in the shoulder region after physical training, 2 had received some previous local injury, and 7 had been lifting or carrying heavy weights previous to their recruitment. In 2 instances serial x-ray examination showed that union was taking place with the development of callus and bone. All the cases occurred in men, and Alderson found no instance of the condition in 3,433 Wrens; it is not, however, confined to the male sex.

The cause of these fractures is not yet established. It is unlikely that they are congenital abnormalities, since the line of fusion of the primary and secondary ossification centres is well behind their usual position in the rib, and sometimes the breaks have been observed to heal, though in other instances non-union and pseudarthrosis result. Lane suggested that trauma might cause the lesion, a heavy blow struck horizontally backwards forcing the clavicle against the first rib. But in these cases a history of trauma is rare. The frequency of the lesion in youth, especially after periods of strenuous physical training, suggests that it may develop gradually, and that the fractures are fatigue or stress fractures of the "march fracture" type. This is the view of Alderson, who also believes that they are sometimes related to the carrying of heavy weights. Hartley,⁶ however, argues that the fractures are usually complete and that frequently there is considerable displacement of the fragments—evidence that muscle-pull does precipitate the fracture. The site of the fracture is certainly where the scalenus anticus is inserted into the rib, and if this muscle contracts violently it will tend to pull upwards the anterior part of the rib while the posterior part is held down by the subclavian artery and brachial plexus. Some observers have called the lesions "cough fractures," suggesting that they are caused by the sudden contraction of the muscle during a fit of violent coughing. This last theory seems the most plausible explanation of this unexpected finding resulting from the routine x-ray examination of the chests of large numbers of apparently healthy individuals.

INDUSTRIAL LIGHTING

Industrial Lighting is the first bulletin published by the Industrial and Welfare Division of the Department of Labour and National Service of the Commonwealth of Australia (37, Swanston Street, Melbourne). It is particularly welcome, as in some respects Australian practice is in advance of that obtaining in this country. Many of the standards formulated in this pamphlet arose from the necessity of war production, and were enforced by statute in new and modified installations in protected factories. It appears that, though not universally compulsory, the standards here advocated have been widely applied. There is much empiricism in these regulations, but a workable scheme emerges in treating the problem as one of distribution of light, of the absence of glare, and the methods for obtaining satisfactory contrast. Australian practice favours diffuse lighting; prominence is therefore given to fluorescent lamps and to standardized cold cathode light. A useful discussion deals with the types of reflectors, screening required at given heights, and the prevention of glare by the use of diffusing filaments. A section on colour gives the range of the paints approved for colour contrast. The suggestion that machines should be painted in light colours is interesting, and fits in with the planned use of colour to aid contrast. The Australian standards have been criticized on the ground that they allow for lower brightness values than is commonly assumed to be necessary. Perhaps the stress here laid on other factors provides a justification for these lower values.

MEDICAL RESEARCH IN MELBOURNE

The twenty-sixth annual report of the Walter and Eliza Hall Institute of Research in Pathology and Medicine is from the pen of the director, Prof. F. M. Burnet, M.D., F.R.S., who succeeded Dr. C. H. Kellaway, F.R.S., two years ago, when Dr. Kellaway came from Melbourne to take up the post of scientific director of the Wellcome Foundation in England. Prof. Burnet, writing in July, 1945, says that during the year under review an effort was in progress to think out and define the new relationships which in one way and another have developed between the Institute, the Royal Melbourne Hospital, and the University. At present there is very little more than physical contiguity between the Institute and the hospital. On the one hand the major lines of investigation by the staff concern problems which are not those of a general hospital, and on the other the demands of the war made it impossible for medical graduates of sufficient calibre to be spared for even part-time clinical research in the wards; it is hoped that once demobilization of the medical services comes into force both the Institute and the hospital will be able again to make full use of their association by developing an active programme of clinical research. If the link with the hospital has been at least temporarily weakened, a more direct link with Melbourne University has been forged by Prof. Burnet's appointment to the newly established chair of experimental medicine. In that capacity he is charged with the organization of a university department within the Institute, its work being naturally determined primarily by the interests of the holder of the chair. Study of the more general problems of the epidemiology of infectious disease will complement the investigations of the laboratory workers in the virus department, and this work should eventually fill an important niche in the field of medical research and teaching in Melbourne. Meanwhile after preliminary discussion with the authorities concerned the Board of the Walter and Eliza Hall Trust has decided that the Institute should be suitably incorporated, and the legal process for this has begun.

might degenerate into the out patient depart

to be bemused into believing that merely to
up doctors there, to provide organized facilities
wards and the dispensing of medicines will of
improvement in medical service. It is some
might well be examined and developed, but
of doctors is necessarily better than an
ly by this physical grouping much is done
is, merely a pretence."

one or two other points relating to
the suggestion in the new White
was capitation payment it should
patients increased—a two a penny—
Another was the restriction whereby
obtained the necessary permission to prac
r area might be prevented by Ministerial
ising in a certain part of that area—say, if in
in a particular ward—which meant that patients
ived of free choice so far as that practitioner was
ned. Yet another was the lack of provision in the com
isation total for loss of capital in respect of professional
premises. The Ministry throughout the discussions on com
pensation had declined to recognize that factor, and if a prac
titioner in selling his house to an incoming practitioner sought
or obtained a price which was substantially higher than its value
as residential premises he laid himself open to fine or imprisonment.

Hospital Ownership

Was the ownership of all hospitals by the State in the public
interest? In future the Minister by virtue of the National
Insurance Bill now before Parliament would become the source
of practically all hospital maintenance income. The Govern
ment would have assumed the responsibility of a compre
hensive service, including the hospital service and would have
become responsible for the cost of hospitals generally. It
would exercise a tremendous influence on hospital development
by reason of that financial power. In the view of the Council
of the Association, to proceed to actual ownership was an
unnecessary and undesirable step.

"It is believed that the effectiveness of a hospital, its responsive
ness to public feeling, its susceptibility to public criticism, the
maintenance of its position as a centre of local interest and welfare
and affection—things essential to humane hospital administration—
will go if in fact the local hospital becomes a State hospital remotely
controlled from Whitehall."

With this destroyed something of lasting value would have
passed out of British life.

There were three administrations in this Bill—hospitals at
the regional level, general practitioner service at the local
executive council level, local authority service at the county
and county borough level. They were bound as a profession to
criticize that vertical division of the health services. It was
bad that much of the work which the general practitioner could
properly undertake in the field of the school medical and the
maternity and child welfare services should be left where it
was. Incidentally under these provisions attendance at con
finements was not necessarily to be a duty upon general prac
titioners, midwives would call in doctors as heretofore, but
only doctors who were "suitably qualified" in obstetrics—the
beginning of the removal of obstetrics from the normal field of
the general practitioner. A branch of the profession which was
cut out badly in this service was the public health medical
service in smaller authorities than counties and county boroughs.

What Does All This Add Up To?

If they believed in a whole time salaried service under the
State, as some of their colleagues sincerely did, they would give
no doubt, a qualified welcome to these proposals, but the
majority of the profession believed that whatever the com
pensation totals, whatever the form of remuneration, they must
search out the principles which lay behind in order to make
sure that the independence of the profession and the freedom
of the public were preserved. The report of the Spens Com
mittee on remuneration was not yet available, but he had no
reason to suppose that it would be unsatisfactory. But was that
the answer they were searching for?

"It is hoped that our profession will be able to examine these
proposals in relation to principles. Will they lead to the submergence
of our profession, the loss of its independence? The answer to that
question must determine our future action."

If they reached the conclusion that these proposals were
contrary to public and professional interest what could they
do? The Government with its majority could carry the pro
posals into law. Clearly the profession must do its utmost
to present its point of view to fair minded people in all parties.
The one hope was in convincing the public that the proposals
were not in the best public interest.

"After all, one cannot help being a little suspicious about these
proposals. For 30 years our profession pressed for the enlargement
and improvement of health services. But when did the interest of
Governments begin? With the publication of the Beveridge report
Sir William Beveridge, approaching these problems as an economist,
saw that to create a social security fund was to create two main out
goings from it, in respect of unemployment and of sickness and he
said quite frankly that before such a fund could be established it
would be necessary to secure a high level of employment (Assump
tion C) and a comprehensive health service (Assumption B). Now
that we have the national insurance proposals in Parliament you will
appreciate how a new impetus was given to the development of the
health service and the desire to exercise control over doctors' cer
tification."

If they were right in detecting the signs of a substantial move
ment toward whole time salaried service then they were at
a crisis in the history of the profession. Once over the line,
with the chance of status the loss of independence, the new
relationship to the State a fundamental alteration would have
been made. It must be clear that this was an issue of public,
not merely of professional interest.

Our profession has nothing to be ashamed of, despite the words
of those of our profession who spend their time belittling it for
political purposes (Loud applause). It has no need to be ashamed
of its contribution to the public good in years gone by. We can
afford to put our position plainly to the public as a matter of public
as well as professional interest, and we must do it."

The Government could legislate but without the co opera
tion of the profession there would be no service. Sooner or
later the profession would have to reach a decision on this
question but the time for decision was not yet. That time
would come when the Bill had become an Act and they could
examine it in its final form. There would be ample time for
the profession to make up its mind. What it was necessary to
do now was to examine these proposals to find out where they
conflicted with public interest and to tell the public. He begged
them now to devote their intelligence rather than their emotions
to an examination of these proposals, not begin to look round
for scapegoats or break up into frictional or fractional groups
or even distinguish between members and non members of the
Association but rather to hammer out their views on this Bill
and make sure that they were points of real principle which
were taken.

My job," said Dr. Hill in conclusion, "is to express as vigor
ously as I can the views of the profession as a whole, and I shall go
on doing that job in the next few months. But it is your job as a
profession to make up your minds on these issues. We are on trial
now. This is the most crucial phase in the history of the profession.
Let us not consider it as a matter of compensation or remuneration.
Let us look at principles and determine where in fact the principles
lie and let us at last learn to stick together." (Loud and long
continued applause)

Questions

Many questions were asked on the details of the Bill. Here,
briefly summarized, are Dr. Hill's replies.

In general, the disciplinary machinery contemplated in the
Bill is the same as under National Health Insurance, ascending
to the Minister.

A doctor in the service who desires to change his area will
make application through his local executive council to the
Medical Practices Committee at the centre. The committee may
or may not permit him to go.

The effect of the proposals seemed at first examination to be
to abolish the status of assistant.

For consultant and specialist appointments a short list was to
be made by an expert committee, so that although the regional
board actually made the appointment, it made it from names of

persons submitted by a well-qualified advisory body. With regard to general practice, the Medical Practices Committee would be predominantly medical; though it should be added that if the system set up was autocratic and destroyed individual freedom it did not matter whether the administrators of the system were medically qualified or not, it was wrong just the same.

One thing which was not yet covered, but which must be ensured, was that where a practitioner was outside the scheme his certificates should be valid for social security purposes equally with those of practitioners within the scheme.

There was nothing to prevent a general practitioner from entering upon or continuing in private appointments—e.g., in works or factories or in insurance companies. These appointments would come within the category of private practice which was permitted under the scheme. But clearly some offices, such as that of district medical officer under the Poor Law, would come to an end.

At the end of the meeting a few three-minute speeches were permitted. Dr. H. R. CRAN suggested that the Council should be furnished with some constructive ideas as alternatives to proposals in the Bill. He thought it should be optional to a practitioner whether he accepted part salary or a larger capitation fee for patients on his list. Dr. KILROE contested the idea that a salaried doctor owed his first obligation to the authority which employed him. Would a tuberculosis officer consider his county council more than his patient? (Cries of "Yes.") That was not his experience. Mr. A. C. DE B. HELME said that not enough stress had been laid on the fact that there had been no negotiation with the Minister. He believed that even now they could if they acted in concert demand negotiation. It was extraordinary what power the Minister took to himself under the Bill. He was made an autocrat, almost a dictator. "If this Bill comes into operation in anything like its present form it will represent something very much like that regime that is now coming to its sorry end at Nuremberg."

Dr. N. E. WATERFIELD said that it was up to them all to get a mastery of the Bill because they could influence public opinion. Dr. WATSON (chairman of Reigate Division) considered that the retention of the goodwill of practices was of fundamental importance. He had in mind especially the case of the elderly man about to retire and the young man coming in. Dr. DAVID HALER drew attention to Clause 69 (3): "Any power conferred on the Minister by this Act to make regulations shall, if the Treasury so direct, not be exercisable except in conjunction with the Treasury." This made the autocracy more complete. It was for the profession to see that it did not pass under Treasury control. Dr. GOUGH, speaking as a young doctor, complained that the view-point of younger doctors was inadequately represented on the Negotiating Committee. He wanted more representation at that level of doctors who had no financial interest in medicine so far as ownership of practices was concerned.

Dr. HILL, in reply to a question, gave some account of how the £66 millions for compensation had been calculated. It had been done by estimating the pre-war aggregate general practitioner income, multiplying by a period of years, and adding a betterment factor. For example, if the aggregate pre-war income figure were taken and multiplied by 1.9 years—a betterment factor of 22% added, or if it were multiplied by 2 years and the betterment factor were 16%, the result in either case would work out to approximately 66 millions. One thing which was important in the division of this money was that those practitioners who had returned from service or had lived in bombed-out areas were entitled to put in not only their current figures but their pre-war incomes. He added, however, that the important demurrer had been made, alike in a letter to Mr. Bevan on March 8 and in the Council's statement of policy on the Bill, that the medical profession was in no way committed to the policy of abolishing the custom of buying and selling goodwill, and although the subcommittee of the Negotiating Committee had entered into discussions on the question of the compensation figure, it did not accept the policy from which the necessity for compensation arose.

The meeting closed after according to Dr. Hill, on the motion of Dr. J. W. STARKEY, honorary secretary of the Surrey Branch, a vote of thanks for "an able, honest, and valuable address."

SOME IMPORTANT CLAUSES OF THE BILL

We print below some of the more important clauses of the Bill which illustrate the power demanded by the Minister of Health. It may be noted that in Section 34, subsection (4), under General Medical Services, a doctor may be able to practice only in part of an area controlled by an Executive Council, a severe limitation on freedom of choice being thus imposed.

1. Transfer of Hospitals to the Minister

6.—(1) Subject to the provisions of this Act, there shall, on the appointed day, be transferred to and vest in the Minister by virtue of this Act all interests in premises forming part of a voluntary hospital or used for the purposes of a voluntary hospital, and in equipment, furniture or other movable property used in or in connexion with such premises, being interests held immediately before the appointed day by the governing body of the hospital or by trustees solely for the purposes of that hospital, and all liabilities to which the governing body of a voluntary hospital were subject immediately before the appointed day, being liabilities incurred solely for the purposes of that hospital.

(2) Subject to the provisions of this Act, there shall also, on the appointed day, be transferred to and vest in the Minister by virtue of this Act all hospitals vested in a local authority immediately before the appointed day, including all property and liabilities held by the local authority, or to which that authority were subject immediately before the appointed day, being property and liabilities held or incurred solely for the purposes of those hospitals or any of them.

(3) If it appears to the Minister that, in the case of any hospital to which the foregoing provisions of this section apply, the transfer of the hospital or of the interests referred to in subsection (1) of this section will not be required for the purpose of providing hospital and specialist services, he may, at any time before the appointed day, serve a notice to that effect on the governing body of the hospital or, as the case may be, on the local authority in whom the hospital is vested, and thereupon the foregoing provisions of this section shall cease to apply to that hospital.

Provided that if the governing body or local authority, within such period (not being less than twenty-eight days from the service of the notice) as may be specified in the notice, serve a notice on the Minister stating that they wish the hospital or interests to be transferred to the Minister, the foregoing provisions of this section shall apply to the hospital.

(4) All property transferred to the Minister under this section shall vest in him free of any trust existing immediately before the appointed day, and the Minister may use any such property for the purpose of any of his functions under this Act, but shall so far as practicable secure that the objects for which any such property was used immediately before the appointed day are not prejudiced by the provisions of this section.

2. Endowments of Voluntary Hospitals

7.—(1) Where any voluntary hospital to which the last foregoing section [section 6 above] applies is, before the appointed day, designated by the Minister under this Part of this Act as a teaching hospital or is one of a group of hospitals so designated, all endowments of the hospital held immediately before the appointed day shall on that day, by virtue of this Act, be transferred to and vest in the Board of Governors constituted under the following provisions of this Part of this Act for the teaching hospital.

(2) All such endowments shall vest in the Board free of any trust existing immediately before the appointed day and shall be held by the Board on trust for the purposes of the teaching hospital generally, and the Board may dispose of any property comprised in those endowments and hold the proceeds thereof on trust for those purposes:

Provided that the Board shall, so far as practicable, secure that the objects of any such endowment are not prejudiced by the provisions of this section.

(3) Where any endowment which is to be vested in a Board of Governors under the foregoing provisions of this section is, immediately before the appointed day, subject to a charge in respect of a liability which would, but for this subsection, be transferred to the Minister under the last foregoing section.

that liability shall, instead of being transferred to the Minister, be transferred to the Board on the appointed day.

(4) All endowments of a voluntary hospital to which the first foregoing section applies, other than a hospital to which the foregoing provisions of this section apply, being endowments held immediately before the appointed day, shall on that day be transferred to and vest in the Minister by virtue of this Act free of any trust existing immediately before that day; and the Minister shall establish a fund, to be called the Hospital Endowments Fund, to which he shall transfer all such endowments.

(5) Regulations shall provide—

(a) for the control and management of the Hospital Endowments Fund by the Minister and for conferring on him any powers required for that purpose, including powers to sell or otherwise dispose of any assets of the Fund and to carry the proceeds into the Fund;

(b) for enabling the Minister to apply, to such extent as may be prescribed, the assets of the Fund for discharging any liabilities transferred to him under the last foregoing section from the governing body of such a voluntary hospital as is mentioned in the last foregoing subsection;

(c) subject to any provision for the discharge of such liabilities, for apportioning the capital value of the Fund among the several Regional Hospital Boards constituted under the following provisions of this Part of this Act, in such shares as may be determined by the Minister in the prescribed manner, and for distributing the income of the Fund to those Boards proportionately to those shares;

(d) for enabling the Minister, on the application of a Regional Hospital Board, to transfer to that Board, for such purposes as may be approved by the Minister, any part of the capital assets of the Fund not exceeding in value the said share of that Board, and for reducing that share accordingly.

(6) Subject to such general conditions as may be prescribed, any income received by a Regional Hospital Board under the last foregoing subsection may be used for such purposes relating to hospital services as the Board thinks fit.

3. General Medical Services

33.—(1) It shall be the duty of every Executive Council in accordance with regulations to make as respects their area arrangements with medical practitioners for the provision by them as from the appointed day, whether at a health centre or otherwise, of personal medical services for all persons in the area who wish to take advantage of the arrangements, and the services provided in accordance with the arrangements are in this Act referred to as "general medical services."

(2) Regulations may make provision for defining the personal medical services to be provided and for securing that the arrangements will be such that all persons availing themselves of those services will receive adequate personal care and attendance, and the regulations shall include provision—

(a) for the preparation and publication of lists of medical practitioners who undertake to provide general medical services;

(b) for conferring a right on any person to choose, in accordance with the prescribed procedure, the medical practitioner by whom he is to be attended, subject to the consent of the practitioner so chosen and to any prescribed limit on the number of patients to be accepted by any practitioner;

(c) for the distribution among medical practitioners whose names are on the lists of any persons who have indicated a wish to obtain general medical services but who have not made any choice of medical practitioner or have been refused by the practitioner chosen;

(d) for the issue to patients or their personal representatives by medical practitioners providing such services as aforesaid of certificates reasonably required by them under or for the purposes of any enactment.

34.—(1) Subject to the provisions of this Part of this Act relating to the disqualification of practitioners, every medical practitioner engaged in medical practice (otherwise than as a paid assistant) who wishes to provide general medical services shall be entitled, on making an application at any time before the appointed day in the prescribed manner to the Executive Council for any area in which he is practising, to be included

in the list of medical practitioners undertaking to provide general medical services for persons in that area.

(2) With a view to securing that the number of medical practitioners undertaking to provide general medical services in the areas of different Executive Councils or in different parts of those areas is adequate, the Minister shall constitute a committee, to be called the Medical Practices Committee, for the purposes of considering and determining applications—

(a) made before the appointed day and by a medical practitioner who is not entitled under the last foregoing subsection to be included in the list of an Executive Council, for inclusion in that list; and

(b) made on or after the appointed day for inclusion in any such list kept by an Executive Council for any area;

and all such applications made in the prescribed manner to an Executive Council shall be referred by that Council to the said Committee, and any medical practitioner whose application is granted by the said Committee shall, subject to the provisions of this Part of this Act relating to the disqualification of practitioners, be entitled to be included in the list.

(3) The Medical Practices Committee may refuse any such application on the ground that the number of medical practitioners undertaking to provide general medical services in the area or part of an area concerned is already adequate, and, if in the opinion of the Committee additional practitioners are required for any area or part but the number of persons who have made applications exceeds the number required, the Committee shall select the persons whose applications are to be granted and shall refuse the other applications.

(4) Except as provided by the last foregoing subsection, the Medical Practices Committee shall not refuse any such application, but the Committee may grant an application subject to conditions excluding the provision of general medical services by the applicant in such part or parts of the area of the Executive Council as the Committee may specify.

(5) The Medical Practices Committee shall be constituted in accordance with the Sixth Schedule to this Act and the provisions of that Schedule shall apply to that Committee.

(6) A medical practitioner who has made such an application as aforesaid which has been refused or has been granted subject to the said conditions, may appeal to the Minister, and the Minister may, on any such appeal, direct the said Committee to grant the application either unconditionally or subject to such conditions as the Minister may specify.

(7) Where the Medical Practices Committee select persons from a number of applicants, the persons selected shall not, during the period for bringing an appeal to the Minister or pending the hearing of any such appeal, be included in the list in question, and on any such appeal the Minister may, if he grants the appeal, direct either that the application shall be granted in addition to the applications already granted or that it shall be granted instead of such one of those applications as the Minister may specify:

Provided that in the latter case he shall make the other applicant a party to the appeal, and no further appeal shall be brought by that applicant in respect of the application in question.

(8) Regulations shall make provision—

(a) for requiring Executive Councils to make reports, at such times and in such manner as may be prescribed, to the Medical Practices Committee as to the number of medical practitioners required to meet the reasonable needs of their area and the different parts thereof and as to the occurrence of any vacancies on the lists of medical practitioners kept by them under this Part of this Act and as to the need for filling such vacancies;

(b) for describing the procedure for the determination of applications by the Medical Practices Committee and for the making and determination of appeals to the Minister under this section, and for requiring Executive Councils and applicants to be informed of the decisions of the Committee and the Minister.

4. Prohibition of Sale of Medical Practices

35.—(1) Where the name of any medical practitioner is, on the appointed day or at any time thereafter, entered on any list of medical practitioners undertaking to provide general

medical services, it shall be unlawful subsequently to sell the goodwill or any part of the goodwill of the medical practice of that medical practitioner:

Provided that, where a medical practitioner, whose name has ceased to be entered on any such list as aforesaid, practises in the area of an Executive Council in whose list his name has never been entered, this subsection shall not render unlawful the sale of the goodwill or any part of the goodwill of his practice in that area.

(2) Any person who sells or buys the goodwill or any part of the goodwill of a medical practice which it is unlawful to sell by virtue of the last foregoing subsection, shall be guilty of an offence and shall be liable on summary conviction to a fine not exceeding—

(a) such amount as will in the opinion of the court secure that he derives no benefit from the offence; and

(b) the further amount of five hundred pounds;

or to imprisonment for a term not exceeding three months, or to both such fine and such imprisonment.

(3) Notwithstanding any other enactment prescribing the time within which proceedings may be brought before a court of summary jurisdiction, proceedings for an offence under this section may be brought either within one year from the date of the commission of the alleged offence or within three months from the date on which evidence sufficient in the opinion of the Minister to justify a prosecution for the offence comes to his knowledge, and for the purposes of this subsection a certificate purported to be signed by the Minister as to the date on which such evidence as aforesaid came to his knowledge shall be conclusive evidence thereof.

(4) Where any medical practitioner or the personal representative of any medical practitioner sells or lets premises previously used by that practitioner for the purposes of his practice to another medical practitioner, or in any other way disposes or procures the disposition of the premises, whether by a single transaction or a series of transactions, so as to enable another practitioner to use the premises for the purposes of his practice, and the consideration for the sale, letting or other disposition is substantially in excess of the consideration which might reasonably have been expected if the premises had not previously been used for the purposes of a medical practice, the sale, letting or other disposition of the premises shall be deemed for the purposes of this section to be a sale by the first medical practitioner or his personal representative of the goodwill or part of the goodwill of the practice of that practitioner to that other practitioner.

Where a medical practitioner or his personal representative sells, lets, or disposes or procures the disposition of, any premises together with any other property, the court shall, for the purposes of this subsection, make such apportionment of the consideration as it thinks just.

(5) Where in pursuance of any partnership agreement between medical practitioners—

(a) any valuable consideration, other than the performance of services in the partnership business, is given by a partner or proposed partner as consideration for his being taken into partnership;

(b) any valuable consideration is given to a partner, on or in contemplation of his retirement or of his acceptance of a reduced share of the partnership profits, or to the personal representative of a partner on his death, not being consideration in respect of past services of that partner or of property of that partner which is transferred or made available to the other partners or any of them for fair consideration; or

(c) services are performed by any partner for a consideration substantially less than those services might reasonably have been expected to be worth;

there shall be deemed for the purposes of this section to have been a sale of the goodwill or part of the goodwill of the practice of any partner to whom or to whose personal representative the consideration or any part thereof is given or, as the case may be, for whose benefit the services are performed, to the partner or each of the partners by or on whose behalf the consideration or any part thereof was given or, as the case may be, the partner who performed the services.

(6) Where any medical practitioner performs services as an assistant to another medical practitioner for a remunera-

tion substantially less than those services might reasonably have been expected to be worth, and subsequently succeeds, whether as the result of a partnership agreement or otherwise, to the practice or any part of the practice of the second practitioner, there shall be deemed for the purposes of this section to have been a sale of the goodwill or part of the goodwill of the said practice by the second practitioner to the first practitioner, unless it is shown that the said remuneration of the first practitioner was not fixed in contemplation of his succeeding to the said practice or any part thereof.

(7) For the purposes of this section—

(a) if a medical practitioner or the personal representative of a medical practitioner agrees, for valuable consideration to do or refrain from doing any act, or allow any act to be done, for the purpose of facilitating the succession of another medical practitioner to the practice or any part of the practice of the first practitioner, the transaction shall be deemed to be a sale of the goodwill or part of the goodwill of that practice by the first practitioner or his personal representative to the second practitioner;

(b) if any medical practitioner or any person acting on his behalf gives any valuable consideration to another medical practitioner or the personal representative of another medical practitioner, and the first medical practitioner succeeds or has succeeded, whether before or after the transaction aforesaid, to the practice or any part of the practice of the second practitioner, the transaction shall be deemed to be a sale of the goodwill or part of the goodwill of the practice of the second practitioner by him or by his personal representative to the first practitioner, unless it is shown that the consideration was not given in contemplation or consideration of such succession to the practice or part of the practice aforesaid:

Provided that this subsection shall not apply to anything done in relation to the acquisition of premises for the purposes of a medical practice, or in pursuance of a partnership agreement, or to the performance of services as an assistant to a medical practitioner.

(8) In determining for the purposes of this section the consideration given in respect of any transaction, the court shall have regard to any other transaction appearing to the court to be associated with the first transaction, and shall estimate the total consideration given in respect of both or all the transactions and shall apportion it between those transactions in such manner as it thinks just.

(9) Where any consideration is, with the knowledge and consent of a medical practitioner or his personal representative, given to any other person, and it appears to the court that the medical practitioner or, if he has died, his estate or some person beneficially interested in his estate derives a substantial benefit from the giving of the consideration, the consideration shall be deemed for the purposes of this section to have been given to the medical practitioner or his personal representative, as the case may be.

(10) A prosecution for an offence under this section shall not be instituted without the consent of the Attorney-General.

5. Compensation

36.—(1) Every medical practitioner whose name is entered on the appointed day on any list of medical practitioners undertaking to provide general medical services shall be entitled to be paid out of moneys provided by Parliament compensation in accordance with this section in respect of any loss suffered by him by reason that he is or will be unable to sell the goodwill of his practice by virtue of the last foregoing section.

(2) The aggregate amount of the compensation to be paid under this section shall be the appropriate proportion of sixty-six million pounds, exclusive of any sums paid by way of interest:

Provided that, if the aggregate number of medical practitioners included on the appointed day in lists of medical practitioners providing general medical services falls short of the prescribed number, the said amount shall be reduced by an amount calculated by multiplying the number by which the said aggregate number falls short as aforesaid by a prescribed amount.

(3) Regulations shall—

(a) prescribe the manner in which and the time within which claims for compensation are to be made, and provide for determining whether any claimant has suffered loss by reason of the matters referred to in subsection (1) of this section and, if so, the extent of that loss;

(b) provide for the distribution of the said aggregate amount among the persons who have suffered such loss as aforesaid, having regard to the extent of their respective losses;

(c) prescribe the manner in which and the times at which the compensation is to be paid, and secure that, except in such circumstances as may be prescribed, it shall not be paid until the retirement or death of the medical practitioner concerned, whichever first occurs; and

(d) provide for paying out of moneys provided by Parliament interest at two and three-quarter per cent. per annum on the amount of the compensation payable to any medical practitioner, in respect of the period from the appointed day until the time when the compensation is paid;

and before making any regulations under this subsection the Minister shall consult such organizations as may be recognized by him as representing the medical profession.

(4) For the purpose of determining the appropriate proportion of the said sum of sixty-six million pounds—

(a) it shall be assumed that provisions corresponding to this section and the last foregoing section will provide for the prohibition of the sale of the goodwill of medical practices in Scotland and for the compensation of persons suffering loss by reason of that prohibition;

(b) the aggregate amount of the losses in respect of which compensation will be payable under this section and under the corresponding provision for Scotland, respectively, shall be calculated in such manner as the Treasury may direct; and

(c) the said sum of sixty-six million pounds shall be apportioned as between England and Wales on the one hand and Scotland on the other, having regard to the said respective aggregate losses, and the amount apportioned to England and Wales shall be the appropriate proportion of that sum for the purposes of this section.

37.—Where the Medical Practices Committee are satisfied, on the application of a medical practitioner or his personal representative, that—

(a) the practitioner has retired from practice or died during the period between the passing of this Act and the appointed day; and

(b) the goodwill of his practice has not been sold in whole or in part before the appointed day;

the last two foregoing sections shall apply in relation to that medical practitioner and to his practice as if his name were entered on the appointed day on a list of medical practitioners undertaking to provide general medical services.

6. Dispensing

39.—(1) Except as may be provided by regulations, no arrangement shall be made by the Executive Council with a medical practitioner under which he is required or agrees to provide pharmaceutical services to any person to whom he is rendering general medical services.

(2) Except as may be provided by the regulations, no arrangements for the dispensing of medicines shall be made with persons other than persons who are registered pharmacists or are authorized sellers of poisons within the meaning of the Pharmacy and Poisons Act, 1933, and who undertake that all medicines supplied by them under the arrangements made under this Part of this Act shall be dispensed either by or under the direct supervision of a registered pharmacist or by a person who for three years immediately before the sixteenth day of December, nineteen hundred and eleven, acted as a dispenser to a medical practitioner or a public institution.

(3) Nothing in this Act shall interfere with the rights and privileges conferred by the Apothecaries Act, 1815, upon any person qualified under that Act to act as an assistant to any apothecary in compounding and dispensing medicines.

7. Powers of Minister where Services are Inadequate

43. If the Minister is satisfied, after such inquiry as he may think fit, as respects any area or part of an area of an Executive Council that the persons included in any list prepared under this Part of this Act—

(a) of medical practitioners undertaking to provide general medical services; or

(b) of persons undertaking to provide pharmaceutical services; or

(c) of dental practitioners undertaking to provide general dental services,

are not such as to secure the adequate provision of the services in question in that area or part, or that for any other reason any considerable number of persons in any such area or part are not receiving satisfactory services under the arrangements in force under this Part of this Act, he may authorize the Executive Council to make such other arrangements as he may approve, or may himself make other arrangements, and for the purpose of such other arrangements he may dispense with any of the requirements of regulations made under this Part of this Act.

8. Powers of Minister to Make Regulations (Clause 69 (3))

(3) Any power conferred on the Minister by this Act to make regulations shall, if the Treasury so direct, not be exercised except in conjunction with the Treasury.

NATIONAL HEALTH SERVICE

GOVERNMENT PROPOSALS TO TAKE OVER VOLUNTARY AND MUNICIPAL HOSPITALS

The following statement has been issued by Lord Latham, Leader of the London County Council.

It is generally accepted that a National Health Service freely available to all is an essential part of any satisfactory scheme of social security and that such a service must include adequate facilities for hospital and similar treatment for all who need it, wherever they may live.

There are at present in this country two parallel hospital systems: the voluntary hospitals, which provide about 77,000 beds, and the municipal hospitals, which provide about 196,000 beds. These figures do not include 189,000 mental hospital beds, almost all of which are provided by local authorities. The Government has decided that the two systems must be co-ordinated into one unified system under national ownership and financed from national funds. To achieve this, the Government proposes to take over all the existing public hospitals, voluntary and municipal, including mental hospitals, and to administer them on a regional basis through Regional Hospital Boards and, for day-to-day management, by local Hospital Management Committees.

It is clear that, since free hospital and ancillary treatment is to be the right of all, towards which all will contribute through the scheme of National Insurance, the Government is bound to provide the necessary facilities and cannot leave one sector of the service to hospitals dependent upon private benevolence, Hospital Savings Association and Hospital Saturday Fund contributions, etc., flag-days and the like. Moreover, when everyone is required to contribute, much of the income from these sources will diminish and ultimately cease for all practical purposes. Thus the voluntary hospitals would not be able to finance the facilities which they will be called upon to provide without becoming increasingly dependent upon contributions from public funds, which will constitute the bulk of their income. Now it is a sound and salutary tradition in this country that where public money is used there must be proper public accountability. Furthermore, the practice of nomination and patronage for entry into voluntary hospitals could not continue side by side with the individual right of every insured person to hospital treatment for himself and his family.

Voluntary hospitals have done fine work and have provided a field for personal service and devoted activity by large numbers of people from all walks of life. But new conditions require new means and ways. There will always be abundant opportunities for voluntary service in many fields of social activity where such service is so valuable. But the proposal to take over the voluntary hospitals involves the future of the

municipal hospitals. Clearly, there cannot continue to be two systems—one of the former voluntary hospitals and another of municipal hospitals. The Government has accordingly decided that it must also take over the municipal hospitals as the only satisfactory way to secure an integrated hospital system, organized on a national basis so as to provide a fair distribution of facilities over the whole of the country, which is far from being the case at present. This will mean that the London County Council will lose its great system of municipal hospitals, which has been welded into a fine hospital service for Londoners, who are greatly attached to and rightly proud of them. They regard them as their hospitals, and so they are. The London County Council has devoted much thought and effort towards making these hospitals—general, special, and mental—the finest in the world. In February of this year big comprehensive plans were approved by the Council for the repair and restoration of damage done by enemy action and for the further enlargement, modernization, and improvement of its many hospitals. It can, therefore, be appreciated with what feelings of regret we shall see them pass from us to the ownership of the State and to their administration by Regional Boards.

I am a local government man; a very large share of my public activities over the past 25 years has been in the field of local government. I believe that local self-government is an essential and valuable part of the governing and administrative structure of this country, which must be preserved if local democracy is to continue and too much centralized government is to be avoided. Encroachment by the central government on the field of local government activities is always regrettable, and appointed Regional Boards are no substitute for popularly elected local authorities. But what is the position that we face? Existing local government units in the country generally do not coincide with what would be satisfactory units for hospital services. Hospital accommodation over the country is inadequate and is also badly distributed in relation to needs: there is concentration in some parts and a grave shortage in many others. In the County of London, for example, there is a large number of both municipal and voluntary hospitals, including twelve teaching hospitals, whereas in other parts of Greater London hospital accommodation is insufficient. If the needs of the people are to be fairly met in the future, existing hospitals must be organized and additional ones located so as to serve much wider areas than the County of London or, maybe, Greater London.

So we must view this matter from the broad standpoint of the greatest service to the greatest number—as I am sure all good Londoners would wish. All persons of good will will agree that if an efficient National Health Service is to be established it must be based upon the provision of hospital facilities for all, with the care and well-being of the patients as the first consideration. With these considerations in mind the Majority Party on the London County Council will support the main principles of the Government's proposals as regards taking over all the public hospitals, voluntary and municipal. The London County Council will, of course, insist that the interests of the people of London are fully safeguarded; that there is adequate representation drawn from the London County Council on proposed Regional Hospital Boards and local Hospital Management Committees, and that in the future administration of the hospitals the needs of the people of London are properly provided for.

Meantime, the London County Council will continue to run its hospitals for the people of London and will pursue with undiminished vigour the work of development and improvement of them.

Londoners are a fine people—their conduct during the war showed this—and I am convinced that they would not wish for narrow selfish reasons to stand in the way of the establishment of a national hospital service freely and fairly available to others in common with themselves. In this supreme matter of the better health of the nation they will be ready to make their contribution—and it is a great one—feeling, however, regretfully, that it is the right and proper thing to do.

LATHAM,

Leader of the London County Council.

The County Hall,

Westminster Bridge, S.E.1.

March 21, 1946.

Correspondence

Foundations of a First-class Medical Service

SIR.—Much of what has been written on the first-class health service for all refers to the sensational subject of "directing" medical talent. An even distribution of doctors through the population is, however, but one of the many reforms entailed. Others, equally pertinent, need prominence.

1. *Numbers.*—The number of doctors needs to be doubled if the essential early diagnosis and efficient treatment are to be meted out to all and sundry. Training a doctor takes about seven years, yet we hear little about schemes to cope with the necessary expansion of the medical schools. Nor shall we raise the standard of our service without doubling the number of our allies of the nursing profession.

2. *Students' Curriculum.*—Medical science, like other sciences, grows prodigiously in this century and in one branch after another. Teachers, consumed with its wonders, have lost a sense of proportion and leave the students no time to develop wisdom and the art of medicine. They assume it is obligatory to pile each new discovery on to the unmanageable load of learning. But much of the detail and of what is new is only of academic interest or useful to the specialist and out of place in the daily round of a family doctor, never entering his mind after he leaves hospital. A radical revision of the syllabus is urgently needed, with diagnosis as the dominant aim, to restore more hours at bedside and out-patient clinics and lessen time at lectures, laboratory, and operating theatre. Mankind's marvels in collective massing and transmitting of scientific knowledge must not make us forget that the brain of the individual remains bounded by an inexpandable cranium. Much of the almost universal contempt for physiology in daily life is due to our obsession with the current outpouring of the products of science. The doctor and the public need arming against the seductive misguidance on the hoardings which makes a mockery of medical education and the salutary prohibition of which has not so far even been hinted at by the Government.

3. *Good Hospital Conditions.*—Even granted a well-balanced training for medical men, bad conditions prevent first-class practice. Constantly having to make shift with low standards and debarred from his proper professional pursuits, a doctor tends naturally to lose enthusiasm and ideals. He longs for the following.

(a) General-practice annexes to hospitals.—He often wants accommodation for patients who need nursing for a few days or weeks. The patient is suddenly ill, requires a bed and waiting on, but, for lack of domiciliary aid, tries to struggle on, with the result that effective application of treatment is uncertain. In another case obscure symptoms call for a few days' close observation under carefully regulated conditions; or initiating a special treatment similarly depends on nursing aid. In every suburb a large house, suitably adapted, with some 20 to 30 beds, would provide the necessary facilities, and yet this is denied the urban doctor, although his country colleague has his cottage hospital. A move in this matter by the Government is another proof we want that a first-class service is in the making.

(b) More general hospital accommodation.—This is woefully short. Thousands of patients, many the victims of cancer, have to wait months and even years with major illness the treatment of which depends on the special facilities and elaborate equipment of large hospitals. A doctor may well wonder whether the effort of diagnosis or consulting with specialists on such cases is justified when it merely leads to a "waiting list." Certainly it seems futile humbug to preach the importance of detecting cancer early, leave alone sending a merely suspicious case to the specialist, when those with late disease are left advancing. Life is at stake; we want plans for the requisite additional accommodation (including that for private patients) clearly foreshadowed before we doctors can believe the words, "a first-class service," are coming true.

What does history teach us? In 1911 Lloyd George's scheme won a place on the Statute Book as a "National Health Insurance." What a fraud, as it catered for only a minority of the people. Don't let the B.M.A. be fobbed off this time merely with the promise of an even distribution of doctors, and let down patients and profession by accepting, as "first-class," conditions of service under which good work is simply impossible. Let our demands for our patients be clear and inexorable. Of course we want equal distribution, but not of

"rotten eggs." The battle with disease is still "on," slaying a few hundred thousand Britons annually; let us apply to the campaign the moral of Field-Marshal Montgomery's words of high praise of the medical services in the Army: "... great work done by our doctors . . . as a result of the immense pains taken our great armies in B.L.A. were far healthier than the armies of the last war.—I am, etc.,

Bristol.

A. WILFRID ADAMS.

B.C.G. Vaccination

SIR.—How fares B.C.G. vaccination against tuberculosis in England? In the Scandinavian countries it has gone from strength to strength since its introduction there about 1927. Its sponsors in these countries have not been obscure, wild-eyed, bagging-at-the-knee enthusiasts but acknowledged leaders in the Scandinavian medical world—Dr. Heimbeck and Dr. Scheel in Norway, the bacteriologist Prof. K. A. Jensen in Denmark, Prof. Arvid Wallgren in Sweden, and many other men with a hard-earned reputation for critical discrimination. It is an illuminating sign of the times that in *Nordisk Medicin* for Jan. 18 of this year Dr. S. Rydén (who deals with some 1,500 vaccinations) says, the stage at which one discussed the risks of B.C.G. having been passed, the questions now remaining to be answered are: whom to vaccinate, and how long does the immunity conferred by B.C.G. last? The papers published in Scandinavia during and after the war on the parenteral administration of B.C.G. have made me wonder what is happening in England now with regard to it. Is it possible that we have been caught napping as we were nearly 30 years ago over the introduction of artificial pneumothorax treatment into England? Has England an intelligent Intelligence Service operating so efficiently that important advances abroad in medicine in general and tuberculosis in particular are promptly brought to the attention of, and if necessary rubbed into, all concerned at home?—I am, etc.,

Leitet, Sunnfjord, Norway.

CLAUDE LILLINGSTON.

* An annotation on B.C.G. vaccination, describing the Norwegian work, appeared in the *Journal* of Feb. 6, 1943 (p. 167). The subject was again reviewed at length in a leading article, "Immunization Against Tuberculosis," in the *Journal* of Dec. 4, 1943 (p. 716), in which we stated this: "To those familiar with the Norwegian work in particular, it may well seem that the experimental period even in man is already over, and that nothing remains but to apply the method at whatever age, on whatever scale, and in whatever classes of persons the circumstances demand." Apparently England has an "intelligent Intelligence Service."—ED., *B.M.J.*

Tuberculin Therapy

SIR.—The obituary notice of Dr. W. Camac Wilkinson (March 2, p. 335) seems to imply that tuberculin therapy has come to an end now that Camac Wilkinson is dead. This is not so. I am still using tuberculin, and getting at least as good results with it as are got by the collapse methods now in use in sanatoria. I say this with knowledge, for I try to keep in touch with all survivors who have suffered from pulmonary tuberculosis in County Down from 1912 onwards, and can compare the results in cases treated in sanatoria with those in cases treated with tuberculin at our dispensaries. The percentage of the latter at work after 5, 10, or more years is quite as good as the percentage of the former.

I agree with Camac Wilkinson that tuberculin has not had a fair trial. The crux of the whole thing is the dosage. This needs to be adapted to each patient, and there are enormous differences in the doses and the ratio of increase of dose that are best in different cases.

In 1932, being the jubilee of the discovery of the tubercle bacillus, the B.M.A. at its meeting in London had a Tuberculosis Section at which a morning session was given to tuberculin in diagnosis and treatment. The opener on treatment mentioned a series of doses which he had used, giving the same series to all patients. This I should expect to do more harm than good, but he concluded by saying that he thought tuberculin was worthy of further trial. Later, when his paper was published in the *Journal*, I wrote pointing out the absurdity of the method of administering tuberculin. But the author replied that if he

were to be criticized in that way he would not use tuberculin any more. This is a fair example of how tuberculin has been abandoned by people prominent in the profession. As a result students are taught that tuberculin is useless and even dangerous, and are given no opportunity of seeing it properly administered. Of course, to use it without knowledge of how it should be employed would be apt to do more harm than good.—I am, etc.,

Tuberculosis Department,
Down County Council, Belfast.

JOHN R. GILLESPIE.

Suprapubic Drainage of the Bladder

SIR.—Mr. E. W. Sheaf's instructive letter (March 2, p. 331) should call for a record of the experiences of other surgeons. Not many will steer so old a patient to safety in such a serious pathological complication.

I always taught that suprapubic puncture of the bladder should be done with a local analgesic and visually—because it presented traps for the unwary to fall into. The first is that the back of the peritoneal fold may be adherent to the bladder, and that surface of it may be torn even without this being noticed. The only evident indication of such an accident may be a slight releasing of the gentle, upward, gauze traction. The second trap occurs if the bladder empties rapidly while the De Pezz tube is being inserted, as may easily happen when some of the causes of such delay are in action. The bladder may then retract off the cannula, and then where are you? The upward and backward direction of the trocar not only is safer but seems to lead to a more rapid closure, by a slow, sliding-shutter action when the catheter is left out.

Thirdly, the best place for puncture seems to be in the middle line just above the pubis, because it suits every size and condition of bladder.—I am, etc.,

London, W 1.

G. H. COLT.

Pathogenesis of Non-specific Mesenteric Lymphadenitis

SIR.—Mr. Ian Aird's communication (Nov. 17, 1945, p. 680) anticipated an article on this subject, now in course of preparation, wherein I shall proceed to elaborate on certain features observed in relationship to "chronic" appendicitis, mesenteric lymphadenitis, and threadworm infestation of the alimentary tract. It was some years ago at the Royal Hospital for Sick Children, Glasgow, that I noticed that every appendix which I removed during the months of January, February, and March, and during the first two weeks in April, of a particular year, contained threadworms, and this was the case even in such appendices as were frankly acute. Mesenteric glands, enlarged to the size of hazel-nuts, were a constant finding in each case, and my interest in the frequency of this association was initiated.

Since then, with an eye on the lookout for threadworms, I have estimated that approximately 70% of these chronic or "normal" appendices, removed during laparotomy because of abdominal pain, tenderness, etc., and associated with mesenteric glandular enlargement, contained threadworms, and during the last few years I have made a point of demonstrating the "threadworm abdomen" to students attending the hospital. Most of these were in the first instance referred by their own doctors to my out-patient clinic as cases of chronic appendicitis. Mr. Aird has given ample details of their symptoms, signs, and preceding history, but I might add that most of them, instead of giving a history of a few previous attacks, complain of many brief attacks of pain over a period of six months to a year, unrelieved by any long intervals of freedom which could be measured in weeks or months. I think Mr. Aird's article passed somewhat briefly over the frequency of nausea and vomiting in such cases—facts which cannot be disposed of lightly when assessing the need for operation.

It should be noted that children suffering from threadworm infestation are not being submitted indiscriminately to operation. Each of these patients is being questioned on such matters as: "Do you get an itchy bottom?" The parents are asked: "Has the child now got, or did the child or any other member of the family have, threadworms at any time?" The examination of the patient includes firm separation of the buttocks to inspect the anus, which sometimes

relaxes into a patent state. Often enough one or more threadworms may appear obligingly to confirm the suspicion of their presence. Cases with a negative history are sent to the ward for an enema, and if the result is negative and other features are not urgent the child is dispatched home, the parent being instructed to observe every motion passed by the child during the following week. Where threadworms are stated to be present, or proved to be so by enema or by observation, medical treatment is instituted. A proportion of these cases continue to complain of abdominal pain in spite of the fact that threadworms have disappeared from the motions, etc., and they are thereupon included in the category of those cases of abdominal pain requiring admission for laparotomy.

To support my contention that mesenteric lymphadenitis (non-specific) is due in the main to the presence of threadworms in the alimentary tract I shall quote from the appendectomy records of one of the two surgical units of the Royal Hospital for Sick Children, Glasgow. The figures for the year 1943 are selected, as during that year reasonably accurate observations were made for the presence or absence of infestation.

226 appendectomies were performed. Of these, 123 were acute, and 103 were chronic or "normal."

Of the chronic 103, 63 contained threadworms. Of the 40 which did not contain threadworms, 6 had previous histories of having had threadworms. Of the 34 without any history or sign of threadworms, 10 case sheets do not indicate that any search was made of the contents of the appendix.

My estimation of the frequency of the association of enlarged glands and infestation is borne out by these figures. Where, on the other hand, the glands are enlarged to the size of a cooked haricot bean, in all probability the aetiological factor is something in the nature of a more acute or virulent infection. To conclude as briefly as possible, the so-called "normal" appendix in threadworm infestation has a characteristic appearance, which, I persuade myself, I can recognize from the outside. Some infestations cannot be cleared up medically, and appendectomy is necessary. Related issues in regard to the foregoing and in regard to the disappearance of symptoms after appendectomy will be elaborated later.

Meantime, in regard to the correspondence which has arisen in response to Mr. Aird's communication, I favour those who for safety's sake perform laparotomy where there are abdominal pain, vomiting, and tenderness in the right iliac fossa and elsewhere, as in less experienced hands many an acute surgical emergency would be misdiagnosed were his precepts too rigidly followed.—I am, etc.,

ANDREW P. LAIRD.

Fractured Bone Graft

SIR,—In the article on survival of cortical bone after grafting, by Mr. David Brown (March 16, p. 389), there is a reproduction of an x-ray film which claims to show union of a fractured bone graft (Fig. 2). In truth the illustration shows an obvious well-marked ununited synostosis with sclerosis on each side. "Fracture" is not quite at right angles to the film, so that it does show through the gap, but the gap is so clear-cut that it is difficult to understand how it could be stated that there is union. In the film of the state of the bone fourteen months after operation one can see the half-inch of the shaft which has not survived as an aseptic sequestrum and will absorb, so producing the radial deviation mentioned. The "fracture" was really the separation of this necrosing bone at its lower end. Close inspection half an inch (1.25 cm.) above this level shows the upper end of the separating fragment and even the outline of the future upper component of the synostosis.—I am, etc.,

FRANK STABLER.

Acute Pancreatitis

SIR,—I was very interested in Mr. Norman Godfrey's article (Feb. 9, p. 203) on acute pancreatitis, and also in the case reported by Mr. Hiren De (March 9, p. 367).

I well recall a female patient of under 40 being admitted to hospital in a state of profound collapse, following a severe attack of abdominal pain. A tentative diagnosis of acute

pancreatitis was made; the urinary diastase index was 500. Any surgical intervention during the state of profound collapse was out of the question, and the patient was treated with morphine to relieve the intense pain, and a glucose-saline intravenous drip. Steady improvement was made and the following day the diastase index was 400, and it continued to fall until it was normal, five days later. Recovery was uneventful, and four months later cholecystectomy was carried out, several stones of the mixed type being present in the gall-bladder. Examination of the pancreas did not reveal any definite abnormality. The recovery of this case so impressed me that I feel it is wiser to abstain from surgery in acute pancreatitis—if one can be satisfied as regards the diagnosis—but many cases fall into that group of acute abdomens in which the precise diagnosis is in doubt, and in these cases operation must be undertaken. This case was treated about twelve years ago and no sulphonamide drugs were used.

I was interested to see that the urinary diastase in the case reported by Mr. Hiren De was 500 on the day after operation. I have several times had the diastatic index estimated in the first specimens of urine passed after laparotomy and drainage for acute pancreatitis, and always found it normal. Had this patient been a little less ill, surgical intervention would have been carried out, with perhaps a less happy ending.—I am, etc.,

Lewisham Hospital

J. JEMSON

Cardiac Beriberi

SIR,—We were most interested to read Dr. Brunel Hawes's letter (March 9, p. 366), in which he stated that the immediate response to thiamine can be regarded as a diagnostic test in a case of beriberi heart. In spite of being unaware of this fact, it was the extraordinary response to thiamine which made us consider that the case we published might have fallen into this category. True the child did not inform us she felt better in three minutes, but this is not surprising as she was suffering from terror and spoke only Polish. Also at first we had to give her B₁ by mouth as we had no concentrated solution for injection. Her whole appearance, however, changed in a few days from one of extreme torpor to comparative well-being while the heart symptoms cleared up and the heart regained its normal size with great rapidity. Hence his letter tends to confirm the opinion which we formed, together with the distinguished Swedish physicians who saw the case.

Several other points in Dr. Hawes's letter we find somewhat intriguing. It is interesting to speculate on the identity of the medical school where in the old days students were constantly ploughed in the finals for bringing up the subject of beriberi and where now they are congratulated by the examiners when they do. We are at a loss to understand, however, why "those stout little girls—housemaids, wardmaids, and probationary nurses—with chlorosis" should have their memory "drowned in a meaningless past," or indeed how a meaningless past can be drowned, or, if drowned, how it can be remembered.—We are, etc.,

P. C. MACCLANCY.

Psychological Reaction to Loss of One Eye

SIR,—The *Journal* of Feb. 2 has just reached me and I have read the article on the above subject by Lady Duke-Elder and Dr. E. Wittkower (p. 155) with great interest. As one who lost his right eye by enemy action in April, 1941, may I be permitted to make some comments upon their views.

If the article were written as "treatment" and for the encouragement of one-eyed patients then its tone would be acceptable, but as a contribution to a scientific journal, to read largely by those having the management of such patients I feel that it is biased on the side of making far too light of the loss of stereoscopic vision.

It is true that it is during the first six months that the difficulty of judging distances is most felt; by the end of that time one has learnt various tips to compensate for the loss of stereopsis such as always to look down on the cup you are filling, never across it. But after nearly five years I still have not devised a method of distinguishing quickly the "insect near" from "the bird far away." Similarly, vision at night, when the

employment of the parallax error to judge distances becomes very difficult, driving or even movement on foot becomes much more hazardous. In spite of the well-intentioned encouragement of scores of friends who say, "Oh, you'll get used to it" I do not feel that anything approaching full compensation of distance-judging can ever be obtained. I suspect those who say it either are not being honest with themselves or were very undiscerning when they hid their two eyes.

I have made no reference to the embarrassment of disfigurement, which admittedly is only great if one allows it to be, but I feel the profession is in danger of being too harsh if it sweeps aside the complaints of monocular persons that they cannot judge distances, and accepts the statement made by the writers that the psychological effect of the loss of an eye is out of proportion to the actual physical disability.

I should very much like to know whether either of the authors has been permanently deprived of stereoscopic vision. I think it is agreed that no man can honestly psycho-analyse himself, and I shall not attempt to assess my emotional reaction to the loss, probably after reading this letter I shall be adjudged as a gross case of class—self-centred, self-pitying anxiety—I am, etc.,

Bombay

PAUL T. MERLIN

Our War Chest

SIR,—The *Journal* of March 9 contains a challenge and a message of hope to all who have the true interests of medicine at heart. The restraint and calm semi-obscenity of the announcement of the Emergency Guarantee Fund contrasts with the publicity it received in several daily papers.

Sir Ernest Graham-Little is only too right in his remarks about the flooding of the medical labour market with suddenly released Service medical officers. As one of them, I find that Ministerial thunderings have made the purchase of a practice or a partnership at this juncture too perilous. Specialization is thwarted because the specialist training posts are engulfed by the same flood, and a married man cannot live on a house physician's salary. Many of us were waiting with disillusioned gloom for the onset of the threatened State medical service as a means, however distasteful, of getting a living. We felt that the B.M.A. would not fight, and the impertinence of Messrs Laski and Bevan encouraged this fear. Now we know where we stand. The profession may not yet be showing its teeth, but it is getting them scaled.

Medicine and politics do not mix. Because the Socialist Medical Association is becoming an example of Socialism rather than medicine we must remain the British Medical Association, not Conservative, Liberal, Communist, or Fascist. If a project concerns medicine we are affected, and should support or oppose it on its merits regardless of its political sponsors.

It may be said that Fund A is not needed. Certainly some of the Opposition newspapers would subsidize our propaganda free. By paying for it ourselves we remain independent, and the public, whose wish in the end must prevail, will see that our motives are non-political. Our hands are very clean. What trade union leaders would "negotiate," as ours have done, with the Minister and keep their promise not to divulge his projects to their own supporters until the Minister has spoken? The present Government has had enough experience of strikes in the most vital industries to know that its chosen weapon of other days is open to all. It is not for the trusted family doctor to become an agitator for any policy. The consulting-room and waiting room are not political platforms. It is different if the patient, interested in the issue as raised in the press or elsewhere, asks for his doctor's opinion. If that opinion is not given unasked it will be respected.

Now we come to Fund B. This is literally the measure of our loyalty, not only to ourselves but to our principles. It is the price we are prepared to pay to gain a new and better medicine instead of bureaucratic slavery. On our support of this fund and the B.M.A. we rest our hopes of a brave new world. It is our chance—perhaps our last one—of raising our prestige to new heights in the eyes of the whole country and of our colleagues throughout the world—I am, etc.,

High Lane

J. L. BROWN

The Minister Listens

SIR,—Dr P. G. S. Davis (March 16, p. 411) contends that "some 40,000,000" of our people are united in the "attempt" to coerce "some 20,000 doctors" into accepting proposals which the vast majority of those doctors sincerely believe will worsen, rather than better, the nation's health and happiness. Dr Davis goes one better than the egregious Prof. Laski, who has declared that he would not allow the House of Lords to interfere with the will of "20,000,000 electors." These wild exaggerations look particularly foolish when one examines the authentic figures. Not more than some 27,000,000 votes were recorded in the last election, and of those only 11,992,222 supported Socialism.

And how should doctors, who are not stonemasons, proceed to "shape a milestone," as Dr Davis, in his penultimate sentence, exhorts them to do?—I am, etc.,

House of Commons

E. GRAHAM LITTLE

Homosexuality

SIR,—The amount of prejudice and extreme emotional reaction engendered by this word is quite remarkable. Surely the solution of the difficulty is to establish an age of consent for boys as well as girls, and, if it seems desirable, increase the severity of punishment for all sexual assault or seduction under this age. This would protect all children of both sexes from premature sexual interference which probably everyone would regard as harmful to their future adjustment to life and society. Such a law would protect boys from corruption not only by their own sex but also by women.

I have recently had a case of a young man about whom I heard twelve years ago, though he himself did not come under my care. At the age of 11 he was seduced by the mother of a school-fellow. Intercourse took place regularly for two years and the lady stated to her friends that he was the father of twins to which she gave birth. Finally in a fit of jealousy she accused this boy of interfering with a girl of 13 without the shadow of proof. This led to the woman being charged, but the court did not see fit, or was not able, to convict her. Not unnaturally the boy grew up to a life of extreme sexual instability and has already served a Borstal sentence for improper conduct.

It is time that all children should be protected from homosexuals of both sexes, but boys as well as girls should be saved from heterosexual experiences such as the one referred to above, which are not so uncommon as some sensitive-minded readers would like to imagine—I am, etc.,

Bath

R. G. GORDON

SIR,—This discussion seems to have reached a stage where an attempt might be made to take a realistic and practical view of the problem. If I am didactic it is for the sake of brevity.

Homosexuality is a state of mind and is ignored by the law. Sodomy is a physical act which in this country is always illegal. A bugger is a sodomite (see *Oxford Dictionary*). Many homosexuals are not sodomites, many sodomites are not genuine homosexuals. If a sodomite keeps the rules which apply to normal intercourse the police will have little chance to intervene.

In all the many cases I have seen as a police surgeon the victim was either unwilling or under the age of consent, or the performance was in a public place. It follows that if the law was altered to place homosexual and heterosexual practices on an equality the change would make little difference in practice, but would go far to scotch the idea that homosexuals as such are persecuted.

Your first correspondent made the astounding assertion that most homosexuals can be cured. If this means that after Nature has adjusted most youths of homosexual tendencies the majority of the residue can be cured, then the statement is untrue. It is even doubtful if psychotherapy has any notable effect. The number of homosexuals is large, but the proportion indicted for sodomy is small. How can it be further reduced? I suggest, (1) by equalizing the law between homosexuals and heterosexuals, (2) by providing first offenders with suitable treatment, (3) by dealing surgically with brutal or persistent offenders—I am, etc.,

Plymouth

S. K. MCKEE

Stethoscope versus X Rays

SIR,—With reference to the correspondence "Stethoscope versus X Rays," which has been pursued so vigorously in your *Journal*, I should like to point out that, in my opinion, the whole controversy is based upon a logical error, for if, on the one hand, the x-ray picture is taken as a faithful representation of structural lesions which we seek to recognize by clinical methods, then this picture must be accepted as the final criterion of truth, with the result that the physical signs (or clinical manifestations) must necessarily be misleading in a certain percentage of cases. If, on the other hand, the physical signs (or clinical manifestations) are taken as the faithful representation of the structural lesions, then they must be considered as the final truth, with the result that the x-ray picture must necessarily be misleading in a certain percentage of cases.

Since, as already mentioned, it is by clinical methods that we endeavour to detect structural lesions—i.e., lesions which, generally speaking, can be strictly defined only by anatomical methods—the diagnosis of these lesions by other than anatomical methods must be based on the correlation of clinical data with anatomical data. Since there has not yet been any reliable statistical work done on the correlation of physical signs (or clinical manifestations) with lesions, or of x-ray pictures with these lesions, it is impossible at present to decide which method gives more accurate results.

This correspondence is symptomatic of the confusion of thought which pervades the whole structure of medicine, and bears witness to the need for a revision of its fundamentals, which in turn would be bound to have a profound influence upon the present medical scheme.—I am, etc.,

Polish School of Medicine,
University of Edinburgh.

ANTONY FIDLER.

SIR,—Dr. F. Kellermann's second letter (Feb. 2) so grossly misrepresents the real issue, and is so contemptuous in its tone, that I crave your indulgence for a few words of remonstrance. No competent clinician would dream of using the stethoscope to the exclusion of all other clinical evidence, nor is it conceivable that this was in the minds of members of the Royal Society of Medicine at their much-discussed debate on Nov. 27 last. As Dr. R. C. Hutchinson said in his letter (Jan. 5), which started this discussion: "Most of the speakers obviously felt the limitations of the title ['Stethoscope v. X Rays'] and included in their remarks the full range of physical examination. Several appear to be thinking in terms of early tuberculosis, in which no one would dispute the pre-eminent value of radiology." Dr. Kellermann says that the subject of the debate "can be summarized in two questions with two simple answers." Let us take each question and answer in turn:

"Question 1.—What evidence of pulmonary disease can be detected by auscultation which could not be detected by x rays? Answer.—Rhonchi and pleural friction-rub." No sound clinician would take "rhonchi" and "pleural friction-rub" as specially distinctive of pulmonary tuberculosis (which is the disease more particularly in question). Does then Dr. Kellermann mean to imply that the other and more distinctive signs, such as crepitations, rales, and wheezes (so often missed because the examiner will take the trouble to get the patient to cough), prolonged expiratory breath-sounds, increased vocal resonance, etc., are never found without x-ray evidence being also always obtained? If so, there are numerous cases—as this discussion has brought out—which disprove such a contention. Further, to depart from tuberculous disease only, auscultation can give evidence of bronchiectasis, where x-ray evidence may be negative.

"Question 2.—What evidence of pulmonary disease can be detected by x rays which could not be detected by auscultation? Answer.—Innumerable." This is bad English, but, letting that pass, would many radiologists and clinicians admit the "innumerable"? This illustrates very well one of the remarks made by Dr. C. A. Birch at the debate: "Instruments passed through three stages: extravagant claims, severe criticism, general use until ousted by a better method." If "the stethoscope was now in the third stage" he might equally well have added: "The x rays are now in the first stage"; i.e., that of extravagant claims. One radiologist of distinction would not agree with the claims made by Dr. Kellermann (see letter from Dr. J. F. Brailsford, March 2), but perhaps in Dr. Kellermann's estimation Dr. Brailsford, although he speaks as a radiologist, is included among those whom Dr. Kellermann contemptuously likens to "a fifth-rate provincial soccer club."

It seems impossible to make Dr. Kellermann understand that those who believe that the stethoscope still has a useful place do not undervalue the importance of x rays. Here is the real essence of the misunderstanding. No good tuberculosis officer to-day would fail to make use of x rays because auscultation gave no evidence, and one would have thought that no competent teacher would allow medical students to suppose that because auscultation was negative, therefore—in a suspicious case—x-ray examination was unnecessary, any more than he would teach that a negative sputum examination meant that tuberculosis was not present. Dr. James Maxwell, Dr. Peter Kerley, and Dr. Geoffrey Marshall must feel grateful to Dr. Kellermann for his support, but in invoking their authority let not the unwary be led to infer that the stethoscope is an obsolete instrument. This is by no means the case. In the report of the debate (*Journal*, Dec. 15, 1945, p. 856) we read: "Dr. Peter Kerley said that the rash statement was made from time to time that the stethoscope was obsolete: no experienced radiologist would agree with that." Dr. James Maxwell, in a reply to Dr. Hutchinson, says: "Nobody would deny that physical examination has its place, but the time has come when physical examination and radiography must be brought together, and teaching must be based upon the intelligent combination of all methods of examination," which would include auscultation. This is a very different attitude from that of Dr. Kellermann.

In short, to quote Dr. Kellermann, "Don't let us confuse the issue," as he himself has done. The question at issue is simply this: Is the stethoscope still useful in cases of suspected lung disease, or is it to be discarded as superfluous, because x rays (as in Dr. Kellermann's view) will give all the information required. His gibes at those who believe the stethoscope to be still useful come with an ill grace from one who is a comparatively recent recruit to the ranks of public health tuberculosis workers. The writer of the letter which initiated the discussion was some years ago medical superintendent at one of our foremost sanatoria (to which, by the way, I believe Dr. Geoffrey Marshall holds the appointment of physician); Dr. Brailsford is a well-known radiologist; and both of these, as well as others who have taken part in this discussion, may well be supposed to have had a very much greater experience of both the clinical and the radiological side of pulmonary tuberculosis diagnosis.—I am, etc.,

Tunbridge Wells.

E. WEATHERHEAD.

Penicillin and Purser

SIR,—Although I entirely agree with Dr. O. P. Clark (March 16, p. 408) that penicillin might well be released in small quantities for general use so that experienced practitioners could use it with advantage in obviously suitable cases, I have perhaps misled him by over-condensing my article about surgery at sea (Feb. 16, p. 244).

The pursers aboard American Liberty and Victory ships, after receiving an intensive course of instruction in advanced first-aid treatment, take an examination which qualifies them as a pharmacist's mate. This peculiar status entitles them to the freedom of the ship's medicine chest, which will always contain adequate quantities of sulphathiazole and sulphadiazine. These drugs are kept almost exclusively for the treatment of gonorrhoea as described in my article. In this and other febrile conditions the exact indications for the use of sulpha drugs and their dosage are laid down in a special handbook, and a purser who tried experiments on his own would probably lose his licence. A further licence is required to give penicillin, and I believe that its use is restricted to the treatment of simple gonorrhoea as described. As there are nearly always some victims of what the poet once called "love's journey" on board, this complaint rather dominates the mental horizon, and it is news to the average purser that penicillin can be a life-saver in acute appendicitis. He would certainly never give it empirically without definite instructions from a rescue ship or visiting doctor, and I have always been required to put my instructions for its use in writing.

Of course the whole scheme derives from the astoundingly rapid development of the American Merchant Navy, and is only justified by the absence of available doctors and by so many emergency cases. In practice it seems to be yielding good results, and the discipline and common sense of the average seaman are well reflected in his careful use of these powerful

drugs I was, however, told that penicillin was freely on sale in many drug stores in the United States at a dollar a shot (10,000 units). In contrast to all this is the medical equipment of our own Merchant Navy, which is based on that obtaining in Nelson's day, while its contents are administered by the captain, mate, or steward, who have had no medical training whatever. Fortunately their minds sharpened by the peril of the sea, invariably seem to lead them to the right treatment in real emergency—I am, etc.,

Walmer

JAMES S HALL

Jittery Legs and Happy Feet

SIR—Perhaps your correspondents on the subject of "jittery legs" would be interested in a brief account of a not dissimilar condition which in its early stages revealed many features in common. I refer to the "painful feet" syndrome which occurred with such frequency among P.O.W.s in the Far East. This distressing condition became a serious scourge within the first year of captivity in Hong Kong, Singapore, and the Philippine Islands in the latter half of 1942, after about six months on a restricted rice and "green stuff" diet.

The sequence of symptoms complained of was

1 A feeling of tiredness in the feet, as though a long walk had been undertaken with tight fitting new shoes.

2 A vague aching which was partially relieved at first by movement—"fidgety feet." This was associated with a tingling sensation, particularly troublesome at night when the increasing severity of the pain prohibited sleep. At this stage there were no abnormal physical signs to be observed.

3 The tingling was progressively followed by a constant "pins and needles," and acute pains described as "burning" or similar to that experienced when first immersing very cold feet in hot water. Some would complain of the whole region from ankle to toes as being very tender, and they would be unable to bear the weight of blankets or wear shoes. Others developed a numbness of the feet, even though the pains continued to become increasingly severe.

4 Sharp shooting spasms would dart up the lower extremity, frequently causing spontaneous groans. This condition became unbearable during the hours of darkness. Relief would be obtained by constant walking about, until utter weariness would permit of short snatches of sleep. Or soaking the feet in cold water would give sufficient respite to enable some rest to be obtained.

It thus became a common sight to see increasing numbers of men limping up and down between the huts, with high steppine clumsy gait, assisting each other, or supporting themselves with sticks, or again small groups rubbing their feet, some sitting face to face, each massaging the feet of a fellow sufferer. A stage then developed when the feet became swollen, flushed, hot, and sweating with general arteriolar dilatation below the knees, or alternatively the lower third of the limb would be cold, swollen, and blue.

Objective symptoms followed: sensory loss affecting first epicritic sensibility, later proprioceptive, ascending stocking wise up the leg. Superficial and deep reflexes were variable—at first exaggerated, then tending towards impairment or loss in the majority, muscles wasted, the men became haggard and emaciated more rapidly than their unaffected comrades, nervously exhausted from pain and loss of sleep.

Late in the year I transferred with a draft containing many such cases to Japan. In that first winter there was great distress from this "painful feet" syndrome which was similarly affecting American P.O.W.s arriving from the Philippine Islands. The cases nearly all showed other manifestations of malnutrition: protein oedema and associated physical signs of avitaminosis, corneal ulceration, stomatitis, cutaneous pellagra and eczema of the scrotum. Men would sleep with their feet exposed to an air temperature below freezing, or immersed in ice-chilled water. Before these practices could be stopped cases were being admitted to my care suffering from gangrene of the toes, or occasionally both feet. Others who had lain for weeks with their knees bent up in order more effectively to massage their affected extremities, developed deformities, and contractures of the leg and vertebral column.

Treatment—Every available type of remedy was tried: rice bran, a fermented flour-sugar mixture believed to contain yeast, various unspecified Japanese vitamin B preparations, a whole host of native black magic methods, while an unrestrainable Japanese "surgeon" performed so-called lumbar sympathectomy upon eight of my patients, with disastrous results in six of them. By the time American

Red Cross medicines, including vitamin concentrates, arrived in 1944 all my cases in Osaka had recovered from the actual "painful feet" syndrome, only the distressing sequelae persisting—loss of toes, or even feet, flat feet, contractures, etc.

This gradual recovery over eighteen months I ascribed to the inclusion of soya beans and barley in the daily ration issued in Japan. I observed no new cases developing in Osaka after 1943 unless they arose in conjunction with a wasting disease—chronic enteritis or pulmonary tuberculosis—in which anorexia led to inability to take even bean congee. No facilities were ever available to investigate these men as they should have been, and all my records and notes on nearly 200 cases were found and destroyed by the Japanese in 1944.

Various names were given to the condition "Happy feet" seemed the most popular among these very courageous lads. The syndrome was undoubtedly part of the multiplicity of malnutritional states with which we became familiar. I personally believed it to be at least contributed to by a deficiency in essential amino acids. No specific factor has been implicated to my knowledge, and one awaits with curiosity the reports of those in a better position to investigate and observe the therapeutic response to vitamins. It is extremely unlikely that tobacco played any part in the aetiology, since supplies of cigarettes were always very limited.

In presenting this brief account of "happy feet" one cannot fail to appreciate the similarities which exist between the immersion foot syndrome and those cases occurring at home reported and observed by Dr. Audrey Roberts and others—I am, etc.,

C. A. JACKSON,

Late Surg. Lieut. R.N.V.P.

London W.C.1

Acroparaesthesia

SIR—Although only nearing 26, and therefore half the age of the cases Dr. J. Purdon Martin (March 2, p. 307) describes, I beg the opportunity to record a personal observation, and submit an explanation. For the last two years on a number of occasions I have experienced numbness in feet, ankles, and calves passing on to intense "pins and needles" before returning to normal. This is always regained by voluntary muscular movements though the knowledge of intense "pins and needles" which I know I shall precipitate has often demanded much effort. The whole episode in my case is over in about five minutes, but nevertheless the condition does have these things in common with the cases described by Dr. Purdon Martin. It always happens some hours after I have taken really severe exercise—i.e. exhausting game of squash or a long walk—and am at rest, absorbed in something. Up till now I have always offered myself this explanation. There has been abnormal pressure on my sciatic nerve or branches thereof, resulting in an interference with the blood supply to that nerve. The factors contributing to the abnormal pressure, which might well apply both to the upper limbs and to Dr. Purdon Martin's bed cases, being fatigue, muscle hypotonia and decreased involuntary muscle movement—e.g. very pleasantly physically tired, absorbed in a book, immobility, decreased muscle tone, pressure on the nerve. An additional perhaps contributing factor I would suggest might also be the change in the metabolism of muscles following exercise, which I believe may take many hours before returning to normal—I am etc.,

M. F. BETHELL,

Surg. Lieut. R.N.V.R.

Physical Therapy in Mental Disorder

SIR—Although I think that the resentment of Dr. J. A. Ansie (March 2) and other psychiatrists at my letter (Feb. 16) was caused by my charging certain of their number with behaving like boys who, having been given an electrical gadget, try it on everybody they dare from the cook to the car—that is to say, with causing unnecessary suffering with cruelty—and that this resentment has been conveniently channelled into indignation on behalf of Dr. Frank, I should like to explain that all I know about this gentleman comes from his own pen.

In a talented paper in the *Proceedings of the Royal Society of Medicine* (May, 1945) he tells us that all the 670 cases undergoing E.C.T. at Graylingwell Hospital "without exception" dreaded it and that "after 15 to 20 sessions a plateau type of over politeness is noticeable which is emotionally shallow and insincere"—that is they are well cowed, that "a pre-

convulsive aura of annihilation is remembered in cardiazol by patients as lasting endlessly whereas its objective time is from 15 to 30 seconds"—that is, with cardiazol you can die a dozen times; that after leucotomy "a submissive over-polite attitude" is seen in all who recovered. From first to last there is no suggestion that these terrors should restrict or stop the treatments, nor, to be fair to Dr. Frank, in the somewhat salamander discussion that followed is any suggestion recorded.

But there is one sentence in this paper which introduces a new, and to my mind an evil, element, and with this I now confront his supporters. It deals with one type of case, forms a paragraph by itself, and is not concerned with the sentences before or after it; in short it is not unfairly snatched from a context: "Coarse hysterical syndrome in primitive personalities, especially when malingering is superadded, responds well to the very powerful suggestion of electric convulsant therapy paraphernalia, but they react in the same way to other similarly suggestive remedies." In other words, show the poor wretch the rack and he or she "responds." But how do these patients know what E.C.T. apparatus is for? In itself it is no more terrifying than a wireless set. And what are the other suggestive remedies? This is the most disturbing sentence I have read in medical literature. I should like to hear what Dr. Ainslie and the Board of Control think of it and all that it implies. It seems to me to strike at the very soul of medicine as it is understood in this country. Here are two points of view between which there can be no compromise.—I am, etc.,

Bexley, Rye, Sussex.

C. G. LEAROLD.

Educating Public Opinion

SIR,—On the occasion of the publication in May, 1944, of the late Coalition Government's White Paper outlining its plans for a National Health Service you were good enough to publish a letter from me in which I ventured to urge the medical profession to resist the plan to socialize it and to bring it under the aegis of the State. There can be little doubt that the energetic steps taken by the B.M.A., and the very strong feelings of suspicion and opposition aroused in the profession, in fact prevented the Coalition Government from proceeding with its plan to introduce a Bill to implement the proposals of the White Paper in 1944. If the profession can resist the financial temptations in the Bill and refuse to co-operate this scheme also will fail or have to be drastically amended.

The object of my letter to you in 1944 was to encourage the profession to resist the plan to transfer its allegiance from the patient to the State. I realize that no encouragement is needed now to induce the profession to resist. I have no doubt that the doctors will fight and, if they do, the doctors will be right.

This Bill now before Parliament represents the maximum results of the alliance between bureaucratic officialdom and anational Socialism. It would be a mistake to assume that it is purely the product of Socialism. Officialdom is its progenitor and Socialism has proved a ready tool. Doctors can be assured of a much more powerful resistance to these proposals from the opposition in Parliament than was apparent in 1944. But the opposition, in spite of all its efforts, will eventually be crushed by the big battalions in the voting lobby. The real battle, therefore, must be in the country, and this the profession must undertake itself, to a very large extent, enlisting the help of laymen wherever possible.

There is an enormous measure of potential support to be had from the public, who will view these iniquitous proposals with profound misgiving if only they are made aware of their full significance. I would respectfully urge those members of the profession who will be taking an active part in the struggle against this Bill to concentrate their efforts upon educating the public in the many directions the patient will suffer, and to refrain as much as possible from emphasizing unduly the manifold ways in which the doctors will suffer also.

It is reassuring to learn that plans for resistance have been well and truly laid, and that a great campaign is to be launched forthwith. This campaign will undoubtedly prove a great strain upon busy medical men, but it must be undertaken in order that public opinion may be educated and aroused from its present apathy. Let the profession take as its motto in this crusade, "Nil desperandum."—I am, etc.,

House of Commons.

GUY LLOYD.

Obituary

SIR JAMES BERRY, D.C.L., F.R.C.S.

Sir James Berry, the news of whose death will be received with regret in a wide circle of old friends and colleagues, was a man of retiring disposition and modest exterior whose qualities of intellect and character brought him, without any seeking on his part, to a foremost position in the medical profession. He was one of those surgeons of whom it can be said that surgery was before all else a vocation; he came to it with a stern sense of duty and a moral sensitiveness recalling Lister's. Beneath his gentle manner was a Puritan spirit.

Born in 1860, James Berry was educated at Whitgift School, Croydon. He received his medical training at St. Bartholomew's and qualified in 1882. His choice and aptitude were for surgery, and he became F.R.C.S. at the age of 25. He was associated throughout his career with the Royal Free Hospital, where he was surgeon for very many years and later consulting surgeon. He was also lecturer to the London School of Medicine for Women, which is linked with that hospital. Other hospitals he served were the Alexandra Hospital for Children with Hip Disease and the Elizabeth Garrett Anderson Hospital for Women.

[Photo: Bassett]

A special line of surgery in which James Berry was a pioneer in the 'nineties was the operation for goitre. He once recalled that when he had performed this operation only eight times he lectured to the Royal College of Surgeons on the subject, and mentioned that two of the eight patients had died. Afterwards, to his indignation, he was reproached by a colleague, who told him that he had made a great mistake in mentioning the two fatal cases. It had never occurred to Berry that any surgeon could possibly withhold publication of his bad results or gloss over them. In his eyes they were as important as, if not more important than, his successes. He was a conservative in the matter of operation. While ready to be adventurous if he saw good foothold, he stood firm against "fashions" in operating. Much of the modern teaching and practice with regard to operative surgery in acute appendicitis he regarded as folly, and he would cite his own early experience of the treatment of appendicitis or perityphilitis in attestation of his point. He believed that most young doctors had a grossly exaggerated idea of the mortality of acute appendicitis when properly treated on common-sense lines. He also stood out against the vogue of unnecessary operation for tonsils and adenoids, unnecessary Caesarean section, large operations for hopelessly incurable carcinoma. Progress in surgery to him was measured, not by the new facility with which operations could be done, but by their life-saving and pain-sparing value for the patient. In the course of his fifty years of active surgical practice he saw a good many idols topple from their pedestals, and his detached and philosophic mind could survey the wreckage with equanimity.

Berry was for several years a member of the Council of the Royal College of Surgeons of England and an external examiner in surgery to the University of Wales. In addition to works on travel, history, and archaeology, he wrote several medical treatises. A book of his on *Diseases of the Thyroid Gland and their Surgical Treatment* was published in 1901, a *Manual of Surgical Diagnosis* in 1904, and, with T. Percy Legg, a work on *Hare Lip and Cleft Palate* in 1912. Sir Henry Butlin's *Operative Surgery of Malignant Diseases*, published in 1900, was "written with the co-operation of James Berry."

One of the outstanding events of his life was his joint headship of the Anglo-Serbian hospital unit which went out to Eastern Europe in 1915. Its purpose was to reinforce other foreign units already in Serbia or about to go there; recruited almost entirely

from the Royal Free, it eventually controlled six hospitals with 360 beds. Berry's first task was to improvise disinfectors and destructors and to attend to the sanitary policing. In his plans for controlling typhus fever he worked on the assumption that typhus was carried by lice, and by lice alone, and though the measures he took were improvised and simple they were completely successful. But presently Serbia was overrun, and the members of the unit fell into the hands of the Hungarians, by whom they were well treated and eventually sent home by way of Switzerland. When the party were discussing with a Hungarian officer their position as a Red Cross unit in enemy hands, the officer admitted that they were neither prisoners of war nor internees, and in reply to their question, "Who are we?" he answered, "Let us say guests," and it was as guests that they were treated. Later they took a Red Cross unit to Rumania, where their work again testified to their energy and enthusiasm. Sir James with his first wife and other members of the unit wrote an interesting book on their experiences, *A Red Cross Unit in Serbia*, published in 1916. After the war Sir James and Lady Berry founded a scholarship to enable women students from Yugoslavia to study medicine in London.

For his services in Eastern Europe he received several decorations, being made a member of the Order of St. Sava of Serbia and St. Anne of Russia, and an officer of the Star of Rumania. He was knighted in 1925. Another honour awarded him was the D.C.L. of Durham. He was President of the Medical Society of London in 1921-2, when he devoted his address to his Balkan experiences, and President of the Royal Society of Medicine in 1926-8. He then retired from surgical practice for the Chiltern Hills but revisited London periodically, and his addresses to his old colleagues—notably an oration to the Medical Society of London in 1932—were examples of retrospection at its best. He suffered from an impediment of speech, a fact which once led him to apologize to a reporter for his difficult experience in "taking him down." In reply the reporter assured him that in fact there was no difficulty at all, for, realizing his infirmity, and with his invariable courtesy towards audiences as towards everyone, he took special pains to speak with deliberation and distinctness.

In 1891 he married Frances May Dickinson, a sister of Lord Dickinson; she was anaesthetist to the Royal Free and the Alexandra Hospital for Children. He and his wife undertook many mountaineering expeditions in the Eastern Alps, the Pyrenees, and the Carpathians, and also on bicycles explored many out-of-the-way corners of Europe. They brought back from their travels large numbers of photographs with which, made into slides, and accompanied by racy commentary, they would entertain their friends in Wimpole Street or give lectures. This knowledge of Eastern Europe stood them in good stead in their subsequent Red Cross missions. Lady Berry died in 1934, and in 1935 Sir James married Dr. Mabel Marian Ingram, also of the Royal Free, who survives him.

SYDNEY G. MACDONALD, M.B., F.R.C.S.

Mr. Sydney Gray Macdonald died in London on Feb. 20 after a short illness. In his passing the profession has lost one of its greatest masters of genito-urinary surgery.

The eldest son of the late Eben MacDonald, he was born in Sydney, New South Wales, on Sept. 17, 1879. Educated privately and at St. John's College, Cambridge, he obtained the degrees of M.A., M.B., B.Ch.Camb. in 1906. He received his medical training at St. Thomas's Hospital, qualified as M.R.C.S. and L.R.C.P. in 1906, and obtained the F.R.C.S.Eng. three years later. His early association with those famous surgeons, the late Sir John Thomson-Walker and Mr. John Pardoe, laid the foundations of his skillful clinical work. He had been house-surgeon at St. Thomas's, senior house-surgeon at St. Peter's Hospital for Urinary Diseases, and surgeon to King George Hospital. His many appointments included those of surgeon-in-charge of the genito-urinary department at the West London Hospital from its establishment in 1920 until 1939, at the Royal Masonic Hospital, and at the Chelsea Hospital for Women. His contributions to medical literature dealt exclusively with his branch of surgery. His best-known work was in connexion with prostatic surgery, amounting to several thousand operations. He was the author of "Diseases of the Bladder" (Latham and English's *System of Treatment*); "Affections of the Urinary Tract" (Fairbairn's *Encyclopaedia*

of Midwifery, 1921), and "Diseases of Kidney and Bladder" (Walton's *Textbook of Surgical Diagnosis*, 1928), and also contributed to the various medical journals. He was a valued member of the B.M.A. and acted as secretary of the Section of Urology at the Annual Meeting of the Association at Newcastle in 1921. In 1930-1 he was president of the Urological Section of the Royal Society of Medicine. He was also a Fellow of the Medical Society of London and the Association of Surgeons of Great Britain and Ireland and a member of the Association Internationale d'Urologie, and had been treasurer of the Society for the Study of Venereal Diseases.

Sydney MacDonald served as captain, R.A.M.C., in France in 1915. In 1919 he married Mary Martineau, third daughter of the late Major-Gen. F. H. B. Marsh, by whom he had one daughter, Prudence. To those who knew him he was a rare character of wonderful integrity and singular charm. Colleagues who have worked with him in close contact over many years testify to his sterling qualities and pay tribute to a great surgeon who ever upheld the best traditions of the profession. He was a strong advocate of medical ethics and would not undertake anything outside his own special province. He was a clinician of the highest order, a convincing lecturer, and a gifted operator whom it was a pleasure to watch at work. Underlying his apparently serious manner was a fund of subtle humour which always delighted and encouraged those who came into contact with him. Always calm, with a determination to see things through, this characteristic was shown when he was stabbed in the back by an unknown assailant during the dark in a London street some years before the last World War. Fortunately the penetrating wound healed without complications.

Indefatigable, and kindness itself, he endeared himself to his patients, numbers of whom have written letters expressing their sorrow and deep sense of loss. So another page in the book of life is written. He was laid to rest in Stonegate Cemetery in the heart of Sussex, the county he loved so well. F. C. E.

D. M. writes: His medical colleagues would agree as to his skill, but I should like to add a layman's testimony to the effect that Mr. Sydney Gray MacDonald was the most modest of men. He was firm yet sympathetic; wise, calm, and unfailingly generous. Above all he was never afraid to say "I don't know." He will be greatly missed, not only in the medical profession, but also by the many patients who owe their lives to him and with whom he seemed always glad to keep in touch.

J. D. ROLLESTON, D.M., F.R.C.P.

Dr. John Davy Rolleston, who died at his home at Kensington on March 13 at the age of 73, was junior by eleven years to his more famous brother, the late Sir Humphry Rolleston; but they had a common interest, and both attained distinction as medical historians and bibliographers. John Davy was born in 1873 at Oxford, where his father, George Rolleston, M.D., F.R.S., was Linacre professor of anatomy and physiology. His mother was the niece of Sir Humphry Davy. He entered Marlborough in 1887, and from there went to Brasenose College, Oxford, as a classical scholar in 1891. His clinical training began at Charing Cross Hospital in 1895. He qualified in 1900, and proceeded D.M.Oxford in 1904. He was made a Member of the Royal College of Physicians in 1926 for his published work, and in 1931 was elected a Fellow.

In 1902 J. D. Rolleston entered the fever hospital service of the old Metropolitan Asylums Board and became assistant medical officer at Brook Hospital. There he made excellent use of the opportunities to develop his knowledge of infectious diseases. In 1914-18 the Grove Fever Hospital, at which he was then serving, was made a military hospital, and Rolleston worked as civil medical officer throughout the war. In 1926 he was appointed a medical superintendent in the M.A.B. infectious hospitals service. Four years later under the Local

(Elliott and Fry)

Government Act the hospitals of the Metropolitan Asylums Board were transferred to the London County Council, and Rolleston remained medical superintendent of the Western Hospital, Fulham, until his retirement under the age limit in 1938. He was not only a careful administrator but an observant clinician. His book *Acute Infectious Diseases* (1925) reached its third edition in 1940. He also published in 1937 a short *History of the Acute Exanthemata*, the substance of his Fitzpatrick Lectures delivered to the Royal College of Physicians in 1935-6. He was the author of several of the sections in the *British Encyclopaedia of Medical Practice*; and much other writing, embedded in medical journals, society transactions, and works of reference, helped to establish his reputation as a keen student of epidemiology. His earliest writing on the subject seems to have been some clinical observations on diphtheritic paralysis contributed to the *Practitioner* as long ago as 1904. He also translated medical works from the French and had a knowledge of other languages, which brought him on to the outdoor staff of our *Epitome of Current Medical Literature*.

His interests in medicine were much wider than the specific fevers. Throughout his career he followed the progress of paediatrics, and from 1910 onwards for many years was editor of the *British Journal of Children's Diseases*. He was a corresponding member of the French Society of Paediatrics. But it was as a medical historian that his pen probably found its most congenial employment, and he was never happier than when describing to a medical society some forgotten episode or piece of biography or showing how some modern discovery or practice had been anticipated in an earlier age. On most days after his retirement he was to be found at his favourite table in the library of the Royal Society of Medicine (of which he was honorary librarian) or of the Royal College of Physicians (where he was a member of the library committee) tracking down some obscure reference or bringing to light some page of history or folklore. His work as medical historian was punctiliously performed, but he had also a lively sense of the odd, the quaint, and the unexpected.

J. D. Rolleston acted as general secretary of the International Congress of the History of Medicine. He was an honorary member of the Royal Rumanian Society of Medicine and of the similar society in France. The diversity of his interests in medicine and the recognition of the work he did in many fields are suggested by his accomplishment of what must be a record—namely, his presidency at different times of as many as four Sections of the Royal Society of Medicine—the Section for Disease in Children, the Clinical Section, the Section of Epidemiology and State Medicine, and the Section of Medical History. He was a member of the British Medical Association for forty years, a Fellow of the Society of Antiquaries, and other interests of his were participation in the management of the Chelsea Physic Garden, membership of the Folklore Society, and active work on behalf of the Society for the Study of Inebriety.

Mr. OSCAR STANLEY HILLMAN, who died on March 16 at Hambledon, was one of the leading surgeons in Portsmouth and the surrounding districts of Hampshire. During the last year or two he had been in failing health and went away for treatment and rest. Born at Bangkok, Siam, on Sept. 26, 1895, he entered the Middlesex Hospital and qualified in 1919, taking the F.R.C.S. in 1921, the M.B., B.S. Lond. in 1922, and the M.S. in 1924. At the Middlesex he served as house-surgeon, senior demonstrator of anatomy, surgical registrar, and casualty surgical officer; he was also lecturer in anatomy at the West London Ophthalmic Hospital and examiner in anatomy for the English Conjoint Board. In 1925 he started his very successful practice at Portsmouth and was elected to the surgical staff of the Royal Portsmouth Hospital and visiting surgeon to St. Mary's Hospital, Portsmouth; he was also consultant to the hospitals at Petersfield and Emsworth. He wrote a book *Operative Surgery Described for Nurses* and published papers on jejunostomy and on the technique of spinal analgesia. In the course of a tribute to Stanley Hillman a colleague has said that his help was eagerly sought, and his crowded clinic at the Royal Portsmouth Hospital and long operating lists at all the hospitals where he worked were a testimony to the esteem in which he was held. Possessed of abundant energy and enthusiasm he had in addition two great qualities that stood out—namely, an intense pride in his work and sympathy in applying it to the relief of suffering humanity. By his early death Portsmouth and its neighbourhood has suffered a most serious loss.

Mr. WILLIAM DOBIE, consulting surgeon to the Chester Royal Infirmary since his retirement from the active staff in 1921, died on March 3 at his home in Chester at the age of 89. Born on May 4, 1856, son of W. Murray Dobie, M.D., of Chester, he was a student at Edinburgh before Lord Lister left for London, and he graduated M.B., C.M. with first-class honours in 1881. After further study at King's College, London, in Paris, Vienna, and Dublin, he became resident house-surgeon and later clinical physician at the Edinburgh Royal Infirmary and was for a year senior president of the Royal Medical Society of Edinburgh, and assistant demonstrator of anatomy in the University. Settling in practice in his native city he was appointed surgeon to the Chester Royal Infirmary in 1907, and for some years acted as medical referee for the Chester district of the London and North-Western Railway and district surgeon for the G.W.R. During the war of 1914-18 he was surgeon to several Red Cross hospitals. He had been a friend of Charles Kingsley and attended Gladstone in his last illness at Hawarden in 1898. A keen student of bird life, he was a member of the British Ornithological Union and president for two years of the Chester Society for Natural Science, Literature, and Art, which awarded him the Kingsley memorial medal in 1897. He joined the B.M.A. in 1884 and served as president of the Chester and North Wales Medical Society in 1899.

The Services

Capt. D. W. Clare, R.C.A.M.C., has been awarded the M.C., and Capt. J. F. S. Walmsley, R.C.A.M.C., has been mentioned in despatches in recognition of gallant and distinguished services at Dieppe in August, 1942.

The Efficiency Decoration of the Territorial Army has been conferred upon Lieut.-Col. (Temp. Col.) R. A. Stark, M.C., T.A.R.O., Major (Hon. Lieut.-Col.) T. T. P. Murphy, and Major W. M. Nichols, R.A.M.C.

Surg. Lieut.-Cmdr. S. E. L. Stening, R.A.N.R., has been awarded the D.S.C. for gallantry and resolution while serving in H.M.A.S. *Perth*, lost by enemy action in the Far East on March 1, 1945.

CASUALTIES IN THE MEDICAL SERVICES

Previously reported missing, now officially presumed to have lost his life on Feb. 28, 1942, in Sumatra waters.—Surg. Cmdr. Thomas Craig Stevenson, O.B.E., R.N.V.R.

AUXILIARY R.A.M.C. FUNDS

The annual general meeting of the members of the Auxiliary R.A.M.C. Funds will be held at 11, Chandos Street, London, W., on Monday, April 8, at 5.30 p.m., when the annual report and financial statement for 1945 will be presented and the officers for the current year elected.

Universities and Colleges

UNIVERSITY OF OXFORD

In Congregation the University has gratefully accepted \$19,000 from the Rockefeller Foundation for research on antibiotic substances under the direction of Sir Howard Florey, F.R.S., professor of pathology.

On March 2 the following medical degrees were conferred:

D.M.—J. L. Pinniger.

B.M.—J. C. Gillett, and (in absence) M. H. C. Williams.

UNIVERSITY OF CAMBRIDGE

At a Congregation held on March 16 Dr. Arthur Leslie Banl received the honorary degree of M.A. and the following medical and surgical degrees were conferred:

M.D.—A. S. Hollins, J. C. P. Grey, G. B. Leyton, A. M. Lester, R. Kauntz, M. Chm.—*B. H. Page, G. C. Martin.

M.B., B.Chm.—*F. S. Hubbersty, *D. G. Davidson, *P. P. Philip, *R. J. Gruchy, *J. E. Pitts, *P. H. Walker, T. A. Evershed, R. I. G. Coupland.

M.B.—*W. E. Tucker.

*By proxy.

UNIVERSITY OF MANCHESTER

George Archibald Grant Mitchell, O.B.E., Ch.M., senior lecturer in anatomy in the University of Aberdeen, has been appointed professor of anatomy and director of the anatomical laboratories in the University of Manchester in succession to Prof. F. Wood Jones F.R.S., F.R.C.S. Mr. Mitchell will take up his duties in September.

UNIVERSITY OF EDINBURGH

The Senatus Academicus of the University has resolved to offer honorary doctorates for conferment at a graduation ceremonial to be held on June 28. The names of two medical men appear in the list—Dr John W. Bone, treasurer of the General Medical Council and of the British Medical Association, and Mr J. W. Struthers, consultant surgeon to the Edinburgh Royal Infirmary and past president of the Royal College of Surgeons of Edinburgh—who are to receive the LL.D. degree, with Prof. Frédéric Joliot and Madame Irène Joliot-Curie for their work on the induced radio activity of common elements, and Mrs Lilian Lindsay, honorary librarian and president elect of the British Dental Association.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At an ordinary meeting of the Council, held on March 14, with Sir Alfred Webb-Johnson, Bt., President, in the chair, a Diploma of Fellowship was granted to David Annis (Liverpool).

Prof. W. E. Gye and Dr. Beatrice D. Pullinger were appointed Imperial Cancer Research Fund Lecturers, 1946. The reappointment of Dr. G. W. Hayward and Dr. H. K. Goadby as Mackenzie MacKinnon Research Fellows was reported, as was the appointment of Dr. H. A. Sissons, of Melbourne, as a Prophit Research Student.

It was decided to hold an exhibition in the College from April 15 to 18 of the prehistoric skeletons excavated from Mount Carmel before the war.

Diplomas in Ophthalmic Medicine and Surgery and in Physical Medicine were granted, jointly with the Royal College of Physicians of London, to the following successful candidates—

DIPLOMA IN OPHTHALMIC MEDICINE AND SURGERY.—S. C. Appleton, J. R. Ascott, J. E. L. Bendor Samuel, K. Fawcett, J. D. Fraser, C. M. Heath, F. G. Hibbert, A. Lindsay, R. G. Macdonald, Violet M. M. McFarlane, Margaret H. E. Martyn, P. H. Merory, J. C. G. Moore, M. L. Nairne, D. F. Ritchie, P. Rosefield, Agnes A. S. Russell, Mary Savory, C. M. Shafio, T. E. Shannon, R. E. Smart, M. W. Smith.

DIPLOMA IN PHYSICAL MEDICINE.—F. B. Niernard, J. Shulman, R. J. F. L. Talbot.

External advisers were appointed to assist the selection committees making appointments to the staffs at Middlesex Hospital, St. Bartholomew's Hospital, and the Coventry and Warwickshire Hospital. The appointments concerned are for general, orthopaedic, oto-laryngological, ophthalmological, and dental surgeons, and for an x-ray diagnostician.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

Honorary Fellowship

On the evening of March 14 the President and Council of the Royal College of Surgeons of Edinburgh held a reception in the Surgeons' Hall at which Mr. James M. Graham, the President (see March 23, p. 452), presented diplomas of Honorary Fellowship to Dr. Andrew Davidson, Mr. Eardley L. Holland, Miss Florence Horsburgh, P. C. Mr. Thomas Johnston, P. C., Sir Edward Mellanby, and Air Marshal Sir Harold Whittingham. The recipients were introduced by their respective sponsors, Sir Henry Wade, Prof. R. W. Johnstone, Miss Gertrude Herzfeld, Principal Sir John Fraser, Prof. J. R. Learmonth, and Dr. Douglas Guthrie.

The Honorary Fellowship was conferred, *in absentia* upon Admiral of the Fleet Viscount Cunningham of Hyndhope, Brig-Gen. Elliott C. Cutler (professor of surgery in Harvard University and chief consultant in surgery, United States Army, European Theatre of Operations), Sir Sheldon Francis Dudley (Medical Director General of the Naval Medical Department), Major-Gen. Paul Ramsey Hawley (chief surgeon to the American Forces in Europe), Prof. Johan Holst (Chief Officer to Royal Norwegian Army, Navy, and Air Force Medical Corps), and Sir Alfred Webb Johnson Bt. (President of the Royal College of Surgeons of England).

At this formal assembly, marked by brilliance and colour, the first to be held in the College for seven years, the President, welcoming Mr. J. I. Falconer, the Lord Provost of Edinburgh, who was among the guests, recalled the happy relations which have obtained between town and College since the Town Council of 1505 yielded to the supplication of the Barber Surgeons and granted to them the 'Seal of Cause,' the initial Charter and the foundation of the most ancient of the Royal corporations. The President, in welcoming the present recipients, explained that, by the laws of the College, the Honorary Fellowship might be conferred on members of the medical profession and on others deemed worthy of the honour, a privilege that had been maintained throughout the generations. Each sponsor then made a short speech of introduction, and each recipient a brief reply. It is noteworthy that Miss Horsburgh, the first woman in the 440 years of the corporation's history to be made an Honorary Fellow, was presented for the distinction by Miss Gertrude Herzfeld, who was the first woman to take her seat as a Fellow of the College.

Medical Notes in Parliament

The Government hopes to take the Second Reading of the National Health Service Bill which was presented to Parliament on March 21, in the House of Commons during the week beginning April 15, although the Conservative Opposition would like a longer time to examine it. No decision has been taken on the number of days to be allotted for the debate. The Conservative Opposition will probably move a reasoned amendment to the second reading and press this to a division.

The Budget will be opened in the House of Commons on April 9.

R.A.F. Medical Service

In the debate on the Air Estimates on March 12 Squad Leader SEGAL said that the £410,000 allotted to the medical services in these estimates was inadequate. The medical branch of the R.A.F. was inadequately represented in the House. That branch and the associated dental branch had played an integral part in the achievements of the R.A.F. Medical research made an essential contribution to both fighter and bomber efficiency in the war. The medical personnel adapted themselves to conditions of sometimes excessive difficulty and stress. A magnificent comradeship developed between the medical officer of a unit and all sections of the unit. To many he was the one remaining link with civil life. Fundamentally he remained a doctor with his first duty to his own profession. Having paid this tribute to the R.A.F. medical branch and having himself been demobilized after six years in the Air Force, he could not omit referring to the waste of medical material in the Force and presumably also in the two other Services. He recalled one instance of an R.A.F. station consisting of only 80 men under the charge of a medical officer but with a large Army general hospital 2½ miles away able to cope with any medical emergency. Doctors who joined the R.A.F. were called upon to deal only with a few of the age groups they would come across in ordinary medical practice. These age groups happened to be the healthiest. These doctors were largely concerned with treatment of only one sex and almost debarred from the treatment of children. During the war the medical officer was not fully occupied and not able to avail himself of the fullest degree of medical practice. On the other hand there was during the war a gratifyingly close association between the R.A.F. medical service and the medical services of the Navy and Army. This reciprocity should be developed in the future. No doctor should be forced to spend his active life working for one of the three Services. At some future date Parliament should evolve one wider medical service which would exchange its personnel among the three Services. The medical organization of our American allies offered a valuable lesson. It provided medical administrators for the administrative side of the service who were not fully qualified doctors. A great saving could be effected in medical personnel by separating the purely administrative side from the medical side. He believed that the R.A.F. had an essential contribution to make to British medicine.

Replying to the debate Mr. STRACHEY said Squad Leader SEGAL must remember that the R.A.F. medical services would cater in 1946-7 for a force reduced below a third of the strength he had known. The proposed expenditure, therefore, might not be inadequate.

Release of Specialists

Mr. LAWSON announced on March 19 that the most up-to-date figures for the numbers of specialists at present retained beyond the release date for their groups were: Navy 7, Army 17, R.A.F. 60. These figures excluded a very small number of specialists who were awaiting replacements due from overseas or had already been nominated for release. The Central Medical War Committee had up to the present received offers or inquiries from 20 practitioners. These were now being examined by the committee.

Allocation of Doctors to the Services

On March 19 Mr. TURTON asked what was the basis of the allocation between the three Services of doctors newly called up and whether consideration was given to the fact that R.A.F. medical officers had, at present, to serve longer than R.A.M.C. officers before obtaining their release. Mr. KEY said the basis was normally the relative strengths of the three Services in medical officers, though circumstances obtaining when the periodical quotas were fixed might necessitate some departure from it. The Government was considering the question of adjusting the provisional distribution for the current half year so as to allow an increased intake to the R.A.F.

Release of Nursing Sisters.—Mr. LAWSON told Mr. Somerville Hastings on March 19 that nursing sisters in military establishments were being released as quickly as possible. Nursing sisters who were surplus to requirements in military establishments in India were either sent to other commands to replace those due for release or returned to the United Kingdom as quickly as suitable accommodation in homeward-bound ships could be provided.

Liquid Paraffin Supplies.—Replying to Mr. Touche and others Mr. LEONARD, for the Ministry of Supply, said on March 14 that production of liquid paraffin, cotton-wool, and other surgical dressings was sufficient to meet all medical needs, but these supplies, particularly liquid paraffin, were used for other than medical purposes. Mr. Wilmot was investigating the distribution of liquid paraffin to see how the position could be improved.

Vaccination of Smallpox Contacts.—Mr. VIANI on March 19 asked why it was considered necessary to vaccinate as well as quarantine suspected smallpox contacts entering this country from overseas, in view of the fact that vaccination after exposure, however early, could be relied upon, and vaccination, even early in the incubation period, might aggravate the smallpox attack if it failed to prevent it. Mr. BEVAN replied that successful vaccination within two days of first contact would entirely protect the majority of contacts, and in any case would mitigate the severity of any attack. He certainly could not accept the last part of the question. He added that vaccination in such cases was purely voluntary.

Notes in Brief

The Board of Trade regrets that it cannot at present make a special issue of clothing coupons to doctors who must equip themselves with white coats and their dispensers with white overalls.

The Disabled Persons Employment Corporation proposes to open the first Scottish factories for severely disabled persons at Cowdenbeath, Dundee, Edinburgh, Glasgow (two), and Motherwell.

The Minister of Fuel and Power has arranged to co-operate in an investigation, recently started in Cornwall by the Medical Research Council, which will include x-ray examination of men employed in tin-mining and tests to determine the preventive and curative effects of inhaling aluminium powder.

The average number of cases attended by Service doctors now in India and Burma is: India, 79,977 daily; Burma, 30,000 daily.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* an increase was recorded in the notifications of whooping-cough 238, and measles 89; there was a decrease in scarlet fever 95, dysentery 28, and diphtheria 24.

A small rise in whooping-cough was observed in most areas of the country, the most notable being Lancashire 48. The incidence of measles in the individual counties showed little variation, with the outstanding exceptions of London with an increase of 185 and Suffolk with a decrease of 108. In the Port Health District of Southampton 54 cases of measles were notified. A small fall occurred throughout the country in the incidence of scarlet fever and no large deviations were reported. There were several relatively large fluctuations in the local incidence of diphtheria; the largest falls were Lancashire 18, Suffolk 12, Norfolk 10, and the largest rises were Hertfordshire 14, Surrey 13, Merionethshire 12. In the latter county 9 cases appeared among the pupils of the County Intermediate School at Towyn. Another 10 cases of paratyphoid were reported from the outbreak in the area of Newport M.B., Isle of Wight.

No fresh outbreak of dysentery of any size was reported during the week. The chief returns were Lancashire 50, London 6, Leicestershire 30, Warwickshire 21, Worcestershire 20, Bedfordshire 16, Northumberland 16.

In *Scotland* the chief feature of the returns was an increase of 253 in the notifications of measles; this rise was due to an epidemic in Glasgow, where 487 cases were reported during the week. Whooping-cough rose from 69 to 117 cases; the principal centres of infection were the cities of Glasgow, Greenock, and Dundee. The total cases of dysentery declined by 11, though there was a rise from 5 to 18 in Dundee.

In *Eire* the notifications of diphtheria fell from 71 to 40 cases—the lowest weekly total during recent months. The incidence of diarrhoea and enteritis in Dublin C.B. remained fairly high with 35 cases.

In *Northern Ireland* the only rise was that of diphtheria, 6; scarlet fever fell by 9 cases.

Week Ending March 16

The notifications of infectious diseases in *England and Wales* during the week included: scarlet fever 1,143, whooping-cough 2,006, diphtheria 475, measles 1,605, acute pneumonia 1,006, cerebrospinal fever 65, dysentery 375, paratyphoid 1, typhoid 6. One of the three cases of smallpox was imported. Deaths from influenza in the great towns numbered 93.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended March 9

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland

Figures of Births and Deaths, and of *Deaths from* *Principal Diseases*, are for: (a) The 126 great towns (London included), (b) London (administrative county), (c) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Rate per 1,000 total births (including stillborn)			29					35		

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

Medical News

Dr Horace Evans, FRCP, has been appointed Honorary Physician to Queen Mary in succession to the late Viscount Dawson of Penn.

A general meeting of the Medical Society for the Study of Venereal Diseases will be held at 11, Chandos Street, W. to-day (Saturday, March 30) at 2.30 p.m., when a discussion on "The Current Trends in the Treatment of Venereal Disease" will be opened by Lieut-Col R. R. Willcox, R.A.M.C.

The annual meeting of the Temperance Collegiate Association, of which Dr R. Cove-Smith is president, will be held on Tuesday, April 2, at 3.30 p.m. in the Hastings Hall at B.M.A. House, Tavistock Square, when Sir Arthur MacNalty will give an address on "The Mirage of Alcohol."

A lecture on "The Realm of Values" will be given by Sir W. David Ross, Provost of Oriel College, Oxford, at B.M.A. House, Tavistock Square, W.C., on Tuesday, April 2 at 7.30 p.m. Free tickets may be obtained from the Director of Studies, British Institute of Philosophy, 14, Gordon Square, W.C.1.

A meeting of the Society of Public Analysts and Other Analytical Chemists will be held at the Chemical Society's Rooms (Burlington House, Piccadilly, W.) on Wednesday, April 3, at 6 p.m., when papers will be presented and discussed.

A clinical meeting of the Medical Society of the L.C.C. Service will be held on Thursday, April 4, at 3 p.m. at St James' Hospital, Ouseley Road, Balam S.W., when members of the staff of the hospital will demonstrate cases.

Plans for restoration and development will be presented at the 46th annual meeting of the Lebanon Hospital for Mental Diseases, Ashfurieh, near Beirut, to be held at the Caxton Hall, Westminster, S.W., on Thursday, April 4, at 3 p.m.

Dr J. Purdon Martin will deliver a lecture entitled "Sciatica and All That" before the Whipp's Cross Hospital Medical Society at the hospital on Friday, April 5, at 8.30 p.m. This lecture was postponed from Feb. 1.

The sixteenth annual general meeting of the Medical Superintendents' Society will be held at the Retreat, York, on Saturday, April 6, at 2.30 p.m. The annual dinner of the Society will be held on the same evening at 6.30 p.m. at the Royal Station Hotel, York.

The next dinner meeting of the Chelsea Clinical Society will be held at South Kensington Hotel, 41, Queen's Gate Terrace, S.W., on Tuesday, April 9, at 6.30 for 7 p.m. when Dr Charles Hill, Secretary of the British Medical Association, will deliver an address on "Medicine and the State."

The National Council for Mental Hygiene (39, Queen Anne Street, W.) has arranged a public meeting to be held at 26, Portland Place, W. on Tuesday, April 9, at 5 p.m., when Miss Gwen Chesters (UNRRA Child Welfare Specialist, Central Headquarters for Germans) will deliver an address on "The Psychological Aspects of Work with Displaced People."

A sessional meeting of the Royal Sanitary Institute will be held at 90, Buckingham Palace Road, S.W., on Wednesday, April 10, at 2.30 p.m., when a discussion on "The Compulsory Notification and Treatment of Venereal Disease" will be opened by Dr J. Greenwood Wilson (who will support the case for compulsion) and Miss Dorothy Manchey (who will oppose it).

The Royal Institute of British Architects is arranging an exhibition at 66, Portland Place, London, W., entitled "Building Now." It will be opened by the Minister of Town and Country Planning on the afternoon of April 11 and will remain open until May 11. By the use of models, drawings, and photographs, the exhibition is intended to illustrate primarily schemes that are still in the design stage, with the addition of work constructed during the war, such as factory welfare centres and wartime housing. There are four sections—housing, health and welfare, education, and municipal administration.

The Scientific and Technical Group of the Royal Photographic Society informs us that the lecture by Thorne Baker on primary colour development, announced to take place on April 16, has had to be cancelled.

The Association of Anaesthetists of Great Britain and Ireland has decided on the publication of a quarterly journal named *Anaesthesia*. Dr C. Langton Hewer has been appointed editor and Dr R. Blair Gould sub-editor. Scientific contributions should be addressed to the editorial offices, c/o George Pulman and Sons, Ltd., Thayer Street, London, W.1.

Until the position in Java is more settled, the Ministry of Health cannot release generally the stocks of quinine which are "frozen" in so many chemists' shops throughout the country. The Ministry has advised the Pharmaceutical Society that if any of its members want to use their quinine they should apply to the Ministry of Supply for a licence.

Sir Alexander Fleming, F.R.S., has been awarded the Harben gold medal for 1946 by the executive committee of the council of the Royal Institute of Public Health and Hygiene. This medal, which is international in character, was instituted in 1894 under a trust created by the late Sir Henry Harben, and is conferred every third year for "eminent services rendered to the public health." Dr J. J. Buchan, medical officer of health for Bradford, has been awarded the triennial "Smith Award" under a trust created by the late Sir William Smith for a medical officer of health who is recognized as having done noteworthy work in the discharge of his official duties.

Among contemporary water-colour painters in the great English tradition must be ranked Robert A. Worthington, F.R.C.S., of Exeter, a memorial exhibition of whose works is on view at the Fine Art Society's Galleries, 148, New Bond Street, until April 12—open from 9.30 a.m. to 5 p.m., Saturday 10 a.m. to 1 p.m. Worthington loved the landscape of England and drew everything with the brush, many of his pictures now shown to the public are of Dartmoor scenery in its changing moods, which he knew well and could portray with exceptional skill and delicacy of feeling.

Dr Jean Matter, medical director of antituberculosis services at Grenoble, is visiting this country, on behalf of French mining organizations intending to establish a rest home for miners on the Côte d'Azur, to study research on and treatment of pneumoconiosis. The British Council has arranged for him to meet British authorities on the subject, and to see miniature maps, radiography work. He is also visiting South Wales to study the subject there.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate* (Western London). ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone, unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors' overseas should indicate on MSS. if reprints are required as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate* (Western London).

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association, TELEPHONE: EUSTON 2111. TELEGRAMS: *Mediseca* (Western London).

B.M.A. SCOTTISH OFFICE: 7 Drumshagh Gardens, Edinburgh.

ANY QUESTIONS?

Butyl and Benzyl Alcohol

Q.—Can you tell me of any health hazards of inhaling air saturated with any or all of the following: *N*-butyl alcohol, benzyl alcohol, *S*-collidine? Is the safe limit of concentration known?

A.—(1) *N*-butyl Alcohol.—The lower volatility of butanol makes it less toxic when inhaled than the lower homologues, but in concentrations above 100 p.p.m. it may have systemic effects, in the form of narcosis, and, though information on this point is not very definite, slight fatty infiltration of the liver. It tends, however, in concentrations above 50 p.p.m. to act as an irritant of mucous membranes, especially of the eye, and recent investigations indicate that it may produce changes in the corneal epithelium—a form of keratitis.

(2) *Benzyl Alcohol*.—This is less toxic than the other alcohol because it is rapidly oxidized and excreted as hippuric acid. It is moderately toxic to animals, producing cardiac paralysis and a low blood pressure, but these effects have not been observed in man. It may produce a skin rash which is very resistant to treatment.

(3) *S*-collidine.—This is a homologue of pyridine (trimethyl pyridine) and has similar effects. These are: (a) Immediate—flushing of the face, rapid pulse and respiration, head ache, giddiness, sleepiness, and irritation of mucous membranes; excitement. (b) After one to two hours—tremor of the limbs, nausea, and vomiting. (c) Prolonged inhalation has produced a picture of "pseudo-encephalitis"—loss of sleep, paralysis of the facial nerve, periods of unconsciousness.

In a series of cases where it was given by mouth in a dosage of 30 to 40 min. (1.8 to 2.4 ml) daily, two developed hepato-renal damage, one fatal, but it has been given safely by

Hæmorrhoids after Confinement

Q.—*A frequent and distressing sequel to confinement is one hæmorrhoid. Advice as to prevention and cure would be welcomed.*

A.—Comparatively few women go through pregnancy and confinement without developing one or more hæmorrhoids. These usually appear during the pregnancy, as a result of the increased vascularity of all pelvic tissues and some interference with venous return occasioned by the tumour. Sometimes the hæmorrhoids remain internal and symptomless during pregnancy, and the effect of labour is to cause them to prolapse and become thrombosed, causing distress in the early days of the puerperium.

Prevention is difficult and often impossible. The important time for prophylaxis is during pregnancy, when the patient should avoid standing as much as possible, and should rest, lying flat or with the foot of the bed raised, for some period in the middle of each day. The bowels should be kept regular, and immediately after defæcation the woman should lie down for a time. There is much to be said for developing the habit of defæcation immediately before retiring at night rather than in the morning. If hæmorrhoids do develop, efforts should be made to prevent their prolapse by firm pressure over the anal canal during the second stage of labour. Any prolapsed hæmorrhoids should be replaced immediately after delivery. This latter, however, is often difficult because the tone of the anal sphincter and perineal muscles is so poor that the hæmorrhoids cannot be retained.

Lymphangitis after Leg Injury

Q.—*Nine years ago a patient aged 54 injured her leg. Ever since then she has had swelling of the ankle and shin, and intense pruritus, most marked at night. Antipruritics have little effect on the area, which appears to be a knot of tender, superficial, thrombosed veins. There is also some varicosity. What treatment can you advise? Is a Trendelenburg operation indicated?*

A.—The question of a Trendelenburg operation arises only in the presence of a continuous and gross varicosity of the internal saphenous vein, and this does not seem to prevail in this case. The accident of nine years ago probably caused either a lymphangitis or a thrombosis, or both, and the leg is left with the tendency to swell, with resulting pruritus in the evening when the swelling is at its height. The only treatment available is a support to the leg to keep the oedema in check, and sleeping with the bed slightly tilted to drain the leg thoroughly at night. The support can be provided by elastic stockings measured to fit the oedema-free leg, or, if the swelling is too severe for this support, elastic bandages serve very well.

Penicillin for Bronchiectasis in Children

Q.—*Have there been any recent advances in the treatment of bronchiectasis in children with penicillin powder?*

A.—Penicillin powder is of value in the treatment of laryngeal infections. In cases of bronchiectasis inhalations of the powder have not, up to the present, proved as satisfactory as inhalations of a mist produced from penicillin solution. The difference in effect is probably due to the larger size of the particle of powder.

Partial Frigidity

Q.—*A young man has come out of the Forces and finds his sexual relations with his wife are likely to lead to estrangement because the act is completed on his part long before she gets any satisfaction. Can you suggest any means of helping them?*

A.—This is a common difficulty and often rights itself in time. In most cases, however, it is necessary to instruct the young man that he should do more wooing, with "love play" and sex stimulation before intercourse. Women are far more dependent upon this than men for satisfactory sex relations. On the other hand, it may be that the wife is partially frigid, either physiologically—from deficiency of endocrine secretions, such as the pituitary—or from psychological inhibitions, or because of such reasons as previous persistent external masturbation, which keeps the centre of stimulation in the clitoris instead of within

the vagina. For the time being artificial stimulation by the husband after coitus may often produce an orgasm in the wife and give some, though not complete, satisfaction.

What is a "Carrier"?

Q.—*A swab showed diphtheria bacilli in the throat of a convalescent woman. On the same day, without notifying the medical or nursing staffs that she was going, she walked out of the isolation hospital and travelled home by train. She has been in the hospital for five weeks. The clerk and chairman of the local authority, in the temporary absence of the district M.O.H., decided to apply to a justice of the peace for a compulsory order to send her back to hospital. The M.O.H. objected on the ground that this person was not "suffering from" a notifiable disease but was a "carrier." I should like a definition of the term "suffering from" as used in the form of notification, and also of the term "carrier."*

A.—A carrier has been defined as a person who without apparent symptoms of a communicable disease harbours an is liable to disseminate the specific micro-organism. In England and Wales the medical officer of health has no power to coerce a carrier as he can a patient "suffering from" notifiable disease, except that he can prohibit the employment of an enteric carrier in any business where food or drink is handled. The point at which a patient ceases to be suffering from the infection and becomes a convalescent carrier obviously varies with different diseases; for example, a child with *Shigella* dysentery may be ill with diarrhoea for only two days but may go on excreting the specific organism for some weeks thereafter. In typhoid fever, on the other hand, the acute infection may continue for weeks, and the patient, if he is still excreting the organism, cannot be classified as a carrier until six to eight weeks after onset. In diphtheria the duration of the acute stage of the illness will vary with the age of the patient, the severity of the attack, the day of infection on which antitoxin was given and how it was given, the type of infecting organism, etc. In this particular case, as more than five weeks had elapsed since the patient was admitted to hospital, it would probably have been difficult to certify that she was still suffering from the disease unless there was evidence of late complications, like post-diphtheritic paralysis. Thus no hard-and-fast line can be drawn between the acute stage of a notifiable disease when the patient is "suffering from" the disease, and the convalescent carrier state when the infectious agent is harboured by the patient without apparent symptoms. It would be wiser to have powers to deal with carriers on the same basis as acute cases as is the law in Scotland.

Pollen and Histamine Azoprotein Injections

Q.—*For the last three years a patient with hay-fever has had a course of Timothy-grass-pollen injections up to 50,000 units. Would any harm be done if a course of histamine azoprotein injections were begun now and continued every five days until the hay-fever season arrived, and if he simultaneously has his graduated doses of Timothy-grass pollen from March until June?*

A.—There is no reason why desensitization with pollen and with histamine azoprotein should not be carried out at the same time.

Malaria Therapy for Tabo-paresis

Q.—*What is the best way to treat a case of tabo-paresis in a man of 50? The dementia is not marked, but is definite. The signs of tabes are well advanced. Apart from some deafness there is no cranial-nerve involvement; the fundi and visual fields are normal. Treatment presumably should be by malaria and trypanamide injections. What are the details of such treatment?*

A.—Certainly induced malaria therapy is advisable. This can be produced either by an intramuscular injection of blood taken from a malarial patient or by a direct bite from infected mosquitoes (from the Ministry of Health). Ten or twelve rigors are usually allowed; the frequency of the rigors (i.e., whether daily or on alternate days) depends upon the strain of malaria employed. Although benign tertian malaria is the usual agent, the rigors often appear every day. Should this prove too exhausting for the patient, 0.2 g. of thiobismol may be

administered after the fever has started. In this way one generation of parasite is killed off, leaving a regular tertian fever.

Careful watch should be kept upon the blood pressure, for premature cessation of the fever therapy may be necessary if the heart's action becomes enfeebled. Retention of urine is a common complication, which may demand catheterization. The malaria is terminated by quinine bisulphate 5 gr. (0.32 g.) t.i.d. for three days; or by an intravenous injection of quinine bihydrochloride 10 gr. (0.65 g.). Mepacrine (atebrin) in 0.1-g. tablets thrice daily is advisable for the next five days. A second course of malaria is often productive of considerable benefit, after an interval of not less than two or three months. An alternative technique (especially in debilitated subjects) is to terminate the malaria with small amounts of quinine after five rigors; and then to resume the malaria after, say, two or three weeks' interval.

In any case malaria therapy should be followed in a week or two by a course of trypanamide and bismuth. The former is given intravenously at weekly intervals, eight injections in all being made; a suitable dosage is 15 gr. (1 g.) twice, 30 gr. (2 g.) four times, and 45 gr. (3 g.) twice. Some authorities give much longer courses, for the risk of permanent damage to vision seems to diminish after the tenth or twelfth injection. The bismuth should be given by twice-weekly intramuscular injections (10 to 14 in all) of any one of the many proprietary preparations. The simultaneous oral use of potassium iodide 10 gr. (0.65 g.) t.i.d. and of liq. hydrarg. perchlor. 1 dr. (3.5 ml.) t.i.d., though out of fashion, is probably useful.

Fluorescent Lighting

Q.—*Fluorescent lighting is becoming more common. In what way does this lighting differ from ordinary electric lighting, and is there any evidence of harmful effects?*

A.—The light emitted by fluorescent lamps is produced not by heating a metal filament to incandescence but by causing an electric discharge to pass between electrodes at each end of a glass tube containing mercury vapour at low pressure. The radiation thus produced has a low luminosity value but a high value in the ultra-violet region of the spectrum, and particularly at a wave-length of 2,537 Angström units. The internal surface of the glass tube is coated with an intimate mixture of three powders, which are excited to fluorescence by the ultra-violet radiation, which is thus converted to visible light.

The powders, and the proportions in which they are mixed, are so chosen that in the case of the most widely used lamp the light emitted closely resembles daylight in its colour-rendering property, in spite of the fact that it gives a line and not a continuous spectrum. Lamps giving differently "coloured" light can be made by using a different fluorescent lining—e.g., in the "warm-white" tube now available the mixture of fluorescent materials is such that the light emitted is richer in red rays than that of the "white" lamp. Fluorescent lamps operate on alternating current, and with the usual supply frequency of 50 cycles per second the lamps are lighted and extinguished 100 times per second; but this alternation is not apparent, nor is it in the case of ordinary filament lamps similarly operated. However, in some circumstances, as in observing moving objects, a stroboscopic effect can be produced by fluorescent lighting, and where this might be objectionable the installation should be so planned that the illumination of such objects is derived from two or three lamps whose light-output cycles are out of phase.

The ultra-violet radiation at 2,537 Å.U. produced by these lamps is not transmitted through the glass of which they are made. The radiation emitted in the near-ultra-violet region is not of shorter wave-length than that found in the solar spectrum, and it is too small in amount to have any harmful effect. More than half a million of these lamps are now in use in this country, and some large-scale installations in factories and other buildings have been in use for the past five years. While some complaints of undesirable effects, usually vague and indefinite in character, have been made, in general it appears that this type of lighting is quite satisfactory and is usually preferred to ordinary electric lighting. Some speculations as to possible ill effects of fluorescent lighting have been published, but no valid evidence of harmful effects is known.

Tar Ointments and Cancer

Q.—*Since tar may cause malignant changes in the skin, is there any danger in the constant use of ung. picis carb. co. in the treatment of psoriasis?*

A.—When this question was submitted about a year ago there was no evidence on which an answer could be based. To provide the evidence ung. picis carb. co. was tested in the laboratory of the Imperial Cancer Research Fund on the most sensitive strain of mice. The results of this test were completely negative, and there is, therefore, no fear of inducing cancer with tar ointments.

Epilepsy and the Encephalogram

Q.—*In cases of idiopathic epilepsy is the electro-encephalogram always abnormal or only at intervals? Does a normal encephalogram exclude the diagnosis of idiopathic epilepsy?*

A.—A normal electro-encephalogram does not exclude the diagnosis of idiopathic epilepsy. The decision whether a record is normal or not depends upon the evaluation of many factors. This means that there is not an absolute norm, but there is now fairly general agreement upon the standards of normality. By these standards about 12% of apparently normal people have abnormal records, as opposed to between 75% and 90% of idiopathic epileptics, depending upon the epileptic population under examination. The younger the patient the more likely is the electro-encephalogram to be abnormal, and in general the more incapacitating the clinical manifestations of the condition the more likely is the electro-encephalogram to show abnormal features.

The electro-encephalogram of epileptics as a rule shows two kinds of changes. One is a continuous disturbance, which may be seen in other conditions, and the other an episodic disturbance, which represents the electrical counterpart of the fit. These episodic disturbances, which often appear without any clinical accompaniment, make the diagnosis of epilepsy certain. They are variable in their occurrence, so that the more frequently records are made in the same subject, and the longer the records, the more likely are they to be seen. With a single short record they are observed in about half of otherwise normal epileptics. If the records are repeated often enough they will be seen in every one.

INCOME TAX

Non-resident Hospital Appointment: Expenses

G. B. intends to take a full-time non-resident post at a hospital "where a car is essential for emergency calls to the hospital." Can he deduct car expenses?

***A.** The general rule is that the cost of travelling between one's residence and the place where the employment is exercised is not allowable—the most obvious case being perhaps the cost of the suburban resident's season ticket to his place of business. We doubt whether the special fact mentioned would serve to take G. B.'s case out of the general rule—the argument would probably be strengthened if the terms of engagement specifically required him to maintain a car.

Liability on India Pay

G. P. left the United Kingdom in September, 1944, and returned in August, 1945. He is told that he is liable as being resident, and ordinarily resident, to British income tax for 1944-5 and 1945-6 in respect of his India military pay. Is that correct?

***A.** On the facts the statement is correct. Tax is payable to both the Indian and British Governments on the India pay brought to or received in this country, but there is provision for some relief from the Indian tax when the British liability is calculated. The fact that British officers receive "family lodging allowances" free of income tax does not affect the liability of people in G. P.'s position.

Repairs to Car

J. R. bought a second-hand car early in 1945; major repairs became necessary involving heavy costs. What can he claim under the Income Tax Act, 1945, apart from the initial and depreciation allowances?

***A.** There seems to be no reason why J. R. should not claim the cost of repairs, except that if the work done on the car was so extensive as to justify the income-tax authorities in holding that as now repaired the car is a different car from the one purchased some portion of the cost of repairing it may have to be regarded as capital outlay.

LETTERS, NOTES, ETC.

Toxic Effects of High Octane Petrol

Dr. J. STEWART LAWRENCE (Bishop's Stortford) writes: With reference to Mrs. Jean Patey's suggestion (Feb. 16, p. 264) and Major J. H. Lankester's note (March 2, p. 342) on poisoning from tetra-ethyl lead in persons exposed to petrol fumes, this question has been very fully investigated in America, and it has been found that petrol as usually handled in commerce carries no risk of lead-poisoning. In all suspected cases so far it has been established that plumbism was not a factor in the production of the illness (Machle, W., *J. Amer. med. Ass.*, 1941, 117, 1965). Only in the cleaning of tanks in which petrol has been stored and allowed to evaporate does this hazard arise, or most commonly in the manufacture of the lead tetra-ethyl itself. That confusion should arise is understandable, for the symptoms of petrol-poisoning resemble closely those of lead tetra-ethyl, including, as they do, abdominal pains, cramps in the limbs, tremors, and hallucinations and violent maniacal symptoms. They are, however, more transient, passing off in 2 to 3 days, whereas those of lead tetra-ethyl, if not fatal, last for 6 to 10 weeks.

Morphine and Adrenaline in Bronchial Asthma

Dr. M. O'BOYLE (Killybegs, Co. Donegal) writes: With reference to the question and answer under the above heading (Jan. 5, p. 38) I have several asthmatic patients in my district, and an injection of 3 to 5 minims of adrenaline during or at the beginning of an attack has no effect on the spasm. I give an injection of from 1 ml. to 1½ ml. of adrenaline during an attack, and have to repeat this in 6 to 8 hours. I have noticed no ill effects apart from slight blanching of the skin. Probably these people have developed a tolerance to adrenaline.

First Aid for Cresol Burns

Mr. D. R. MATTHEWS, M.P.S., pharmacist, Middlesex Hospital, writes: I read with interest the reply to the query relating to the first-aid treatment of cresol burns (Feb. 2, p. 191). It has always been my practice to deal with liquid phenol splashes by immediately swabbing the area with cotton-wool soaked in industrial spirit and wiping off rapidly. This immediately allays the stinging sensation, and the skin at once recovers its normal appearance, leaving none of the usual eschar. The method was once applied to an extensive area, involving the whole of the forearm, and was commended, presumably on its effectiveness, by those who subsequently dealt with the patient. An experiment with small applications of cresol to the underside of the forearm confirms the usefulness of the method. Washing with water or sodium bicarbonate solution proves ineffective in allaying the sting or preventing erythema, while the application of spirit accomplishes both. I presume the better result obtained by the latter treatment is due partly to the readier solubility of the phenols in alcohol and partly to the lower surface tension of alcohol by comparison with water. Rapid circumscribing of a splashed area with the spirit in conjunction with the release of cotton-wool pressed on the splash itself would have the added advantage of withdrawal of most of the phenol therein, as in the technique of grease-spot removal. While some phenol might be the more readily absorbed in the alcoholic solution, it appears that its penetration might be obstructed somewhat by any slight coagulum of protein formed, such natural protection being enhanced by the hardening effect of the spirit. Meanwhile the withdrawal of the major portion of the phenol is accomplished via the porosity of the wool. For minor splashes, at least, the "spirit" removal is of undoubted value as a first measure. The antiseptic value of the spirit is also advantageous.

Phenol and Cresol Burns

Mr. L. T. RINDER (Barking) writes: As safety officer to the largest producers of phenol and cresylic acids in this country, and as a member of the Royal Society for the Prevention of Accidents, perhaps you would allow me to amplify the answer already given. After much experience of chemical cures of almost every type, I am convinced that, with the exception of metallic sodium, water and plenty of it is by far the best treatment for the first-aid to adopt. It is not, however, sufficient to give just a hasty swill under the tap. Water should be allowed to flow over the burnt area for at least ten minutes, and longer if possible. The question of extensive phenol burns is a much more serious problem and demands the earliest possible medical attention. Apart from the necessity for dealing adequately with the effects of shock, there is the grave possibility that a lethal amount of the poison may be absorbed through the damaged tissues.

A Road Accident Syndrome?

Dr. E. GRANGER (Thame, Oxon) writes: On looking through the table of vital statistics in the *Journal* one is struck by the omission of what is hardly a notifiable disease, perhaps, but is nevertheless the most potent cause of death that modern civilized man is heir to—namely "automobilism." Whether this is a disease in itself is a

matter of opinion, but it is undoubtedly a precursor of various mental and physical aberrations. When one thinks of the time, energy, brains, and money that have been expended on combating diseases far less lethal than the road locomotion syndrome, it is nothing less than staggering that so little research has been undertaken on the above scourge when the cost of it would be infinitesimal compared with the appalling loss of life and injury. The lack of interest in alleviating these distressing complications can be largely explained by an attitude of fatalism. A child chooses to dash in front of a moving car without due deliberation; the steering suddenly fails due to some mechanical failure: these two cases can perhaps be regarded as fate and there is practically no cure for them. But for every one of these there are at least 10 other cases where the lapse lies with the driver, not with the car, and only partly with any third party. It is by the intensive study of these lapses that much could be done to lessen the fatality. In the R.A.F. much good work has been done by interrogating air-crews involved in crashes. I suggest as a beginning that the R.A.C., the insurance companies, or some other interested body should employ an average driver of average physique and capable of analysing his reactions to circumstances. Over a period of years he should drive various cars over various roads: long and short distances, day and night, in both town and country. He should keep a log of all accidents, near misses, and "might-have-beens"; what he was thinking at the time; what in his opinion caused the aberration. Was he thirsty, full, or hungry? Was the car running well or ill? Was it noisy? What was the light like? Was he cold, hot, tired, or too comfortable? Was he on a straight fast road or one with many bends? Had he been driving all day or had he just started? What was the state of his health: blood pressure, pulse, alimentary activity, and any other relevant details? There should be notes on his reaction to various drugs—ephedrine, benzedrine, alcohol, and others. Surely if this investigation were carried on long enough, and the investigator travelled far and sometimes fast enough, provided always he managed to survive and kept his mind, eyes, and ears open, something would come of it, and additional light be thrown on this very pressing problem.

The Lanes Tuberculosis Scheme

Dr. F. C. S. BRADBURY writes: In your issue of March 9 you kindly reviewed Dr. Lissant Cox's annual report for the year 1944 under the above title. As successor to Dr. Cox may I draw attention to a couple of inaccuracies which appeared therein. It is stated in the first paragraph, third sentence, "... and in 1934 over 30% of pulmonary cases on the register..." This should, of course, have read "... and in 1944..." The third sentence of the second paragraph reads "... and the resultant long waiting list of over 1,000 patients." The county waiting list for 1944, averaged at monthly periods during the year, was 106 (see page 15 of Dr. Cox's annual report).

"B.M.J." for Hungary

To the growing number of appeals for British medical literature from the countries of Europe must be added one from Hungary. There is a dearth in Hungary of current literature on English medicine, and Mr. Edward Fuller, editor of *The World's Children* (20, Gordon Square, London, W.C.1), asks for copies of the B.M.J. He writes: "It occurs to me that some of your readers may be moved to pass on any copies they do not habitually file."

Correction

The thirteenth line of Prof. Grey Turner's memoir of Adolf Lorenz of Vienna (March 23, p. 453), should have read: "At the Allgemeines Krankenhaus he only had an out-patient department..."

BIRTHS, MARRIAGES, AND DEATHS

The charge for an insertion under this head is 10s. 6d. for 18 words or less. Extra words 3s. 6d. for each six or less. Payment should be forwarded with the notice, authenticated by the name and permanent address of the sender, and should reach the Advertisement Manager not later than first post Monday morning.

BIRTHS

BHAGEERUTTY.—On March 21, 1946, to Catherine, wife of Dr. Bhageerutty, of Norton Canes, a son—Jan Dorian.
WRIGHT.—On March 22, 1946, at the Manse, Henrietta Gardens, Bath, to Sheila Wright, M.B., Ch.B. (née Richardson), wife of Capt. Frank B. Wright, a daughter.

DEATHS

HILLMAN.—On March 16, 1946, Oscar Stanley Hillman, M.S., F.R.C.S., at his home, Cherry Copse, Hambledon, Hants.
JOHNSTON.—On March 17, Benjamin Rigby Johnston, aged 84. Practised at Grasmere since 1887 continuously.
MARSHALL.—On March 15, 1946, at Parkend Cottage, Wishaw, Lanarkshire, Thomas Burns Marshall, M.B., C.M., husband of the late Mary Swan Falconer.

SURGICAL ASPECTS OF CONGENITAL HEART DISEASE*

BY

A. RAE GILCHRIST, M.D.Ed., F.R.C.P.Lond.

Physician, the Royal Infirmary, Edinburgh

There is a new outlook in congenital heart disease. Overburdened in the past with embryological detail and developmental complexities, the study of congenital cardiac malformations has received in recent years a fresh impetus from renewed clinical and radiological studies, and particularly from the brilliant achievements of the surgeons working in this field. To share in these advances the family doctor will take note of the contributions which surgery is now making. His is the first opportunity to establish the diagnosis and to advise regarding treatment. It is my intention to present a brief account of the congenital defects at present considered amenable to surgical correction. Of these there are two—the patent ductus arteriosus and coarctation of the aorta—both, fortunately, easy of detection by simple clinical methods.

For the most part congenital heart disease is occult. All too frequently it remains undetected throughout childhood, masquerades in adult life as an acquired lesion, or, deceptive until the end, reveals itself only at necropsy. Dismiss from consideration the weakly puny infant, cyanosed even to a deep plum colour, for whom death comes as a merciful relief. Such a conception of congenital heart disease is inadequate, for cyanosis with its attendant finger-clubbing and poor physique is more often the exception than the rule. In childhood there is usually no gross manifestation of the underlying defect. Symptoms in the usual acyanotic patient are generally minimal or absent, though admittedly they are liable to flare into prominence when serious and perhaps irremediable complications develop. Nowadays, when aetiology plays so large a part in the comprehensive diagnosis of heart disease, the probability of a congenital lesion even in the adult must be thought of more often and sought for by definite methods.

If surgery is to play its full part in the prevention of invalidism and early death, every endeavour must be made to establish the nature of the anatomical flaw during childhood, and preferably before 10 years of age. Repair of the defect in early life permits normal growth and development and safeguards the individual from the killing complications. In the child the surgeon will obtain easier access to the lesion, and, as the mortality rate for intrathoracic intervention increases with each decade (Edwards, 1939) it is a sound principle to advocate early recognition and correction of the congenital flaw.

The Patent Ductus

In foetal life the most distal part of the aortic arch beyond the origin of the three main trunks is united by the ductus arteriosus to the main stem of the pulmonary artery at the point of its bifurcation. Blood expelled by the right ventricle is conveyed via the pulmonary artery, ductus, and descending aorta to the placenta.

When the ductus fails to close blood flow through it is reversed, the work of the heart increased, and with the passage of time physical signs develop so that as a rule by the age of 1 or 5 years the diagnosis can be established with confidence. Symptoms are trivial, but a noteworthy murmur, systolic-diastolic in time, characterized by its continuous quality and

maximum in intensity at a site a little below the inner end of the left clavicle, develops as a rule by the time school age is reached. To the trained ear the recognition of the murmur is simple, and the diagnosis can be established readily by the detection of this remarkable physical sign, well entitled to the name of the Gibson murmur.

When the leak from the major circuit to the pulmonary artery is large—and it may amount to 50% or more of the left ventricular output—the heart enlarges, but the most striking changes occur in the pulmonary artery, which dilates to accommodate the increased blood-flow (Figs 1 and 2). The lung fields become more vascular and the diastolic blood pressure falls. Physical exertion aggravates these signs. The murmur then becomes louder and roaring in quality, and the diastolic pressure drops to even lower levels but returns to its former figure usually within a minute of completion of a simple exercise test. For the time being the patient may present all the outward appearances commonly associated with a free aortic regurgitation—pallor, bounding neck vessels, the Corrigan pulse and even capillary pulsation. This test, described by Bohn (1938), can be applied on occasion with advantage but unfortunately readings of diastolic pressure are difficult to obtain in a child under 5 years, when in the absence of the fully developed Gibson murmur a positive test would be of most value. In older children or younger adults an exercise test may prove helpful in the elucidation of pulmonary systolic murmurs of doubtful origin.

It has been estimated that the presence of a patent ductus reduces the expectation of life by half even among those surviving to age 17 (Keys and Shapiro, 1943). Clinical experience indicates that this defect is seldom encountered after the age of 40, the commonest complication being a bacterial endarteritis of the pulmonary artery—until recently a uniformly fatal disease. This is an infection exactly analogous to bacterial endocarditis but localized in the first instance to the damaged intima within the pulmonary artery immediately opposite the mouth of the patent ductus. A swinging temperature, patchy pulmonary signs attributable to multiple lung infarcts, and a localized Gibson murmur, then sometimes heard best towards the mid-clavicular region, are the main components in an important diagnosis which can be confirmed by positive blood cultures and by repeated radiological examinations of the chest (Gilchrist, 1945). Surgical ligation of the ductus promises a prompt recovery in at least 50%. Medical measures such as prompt transfusions, sulphonamides and penicillin have little to offer and are not in themselves to be regarded as curative.

Is it not better to attempt to forestall the killing complications of the patent ductus by ligating the channel in early life, when the child is relatively fit and capable of withstanding this intrathoracic procedure, than to wait to a later age when in the presence of a blood-stream infection and multiple lung infarcts, the operative risks are ten times as great? Early ligation permits normal growth, encourages an adequate nutrition and prevents the development of a local infection without the handicaps of an uncertain invalidism which, extending over the years, becomes quite frequently the basis of a cardiac neurosis. With ligation successfully accomplished the child can approach

* An address delivered to the York Medical Society on Dec. 1, 1945.

adult life with confidence and with full expectation of an unimpaired physical capacity.

Differential diagnosis seldom gives rise to difficulty. Cyanosis is not a feature. Clubbing of the fingers does not occur. The auscultatory signs are restricted to the region of the pulmonary artery, and though a systolic murmur, a prominent and over-active pulmonary artery on cardioscopy, and a positive exercise test might together suggest the diagnosis in the absence of the Gibson murmur, yet surgery would not be justified were this distinctive auscultatory sign consistently absent.

Ligation of the Ductus

The surgical procedure is less formidable than might be supposed. Children stand the operation well. The original transpleural approach devised and perfected by Gross (1939a, 1939b, 1944) has been modified by Touroff (1942). Increasing experience of the advantages of subadventitial dissection on the arch of the aorta, as advocated by Touroff, fully substantiates his claim that this procedure reduces the likelihood of injury to the flimsy-walled ductus, simplifies and shortens the operation, and facilitates the application of the ligature as close to the aorta as possible, thereby reducing the likelihood of recanalization. Ligation by this method appears preferable

haemorrhage from a torn ductus and one from mediastinal sepsis. A large measure of compensation for these two bitter disappointments has been found in the remarkable benefits already obtained in the group of 14 surviving patients. For a variety of reasons ligation has not so far been undertaken in 20 of our patients. Shapiro and Keys (1943) collected 107 non-infected cases. Ligation was completely successful in 81, and 9 patients died at or shortly after operation. After the age of 10 operative mortality increases year by year, so that over the age of 20 surgery can be justified only if symptoms are severe enough to warrant the risk. At the other end of the scale it is desirable to postpone intervention until the duct has had every opportunity to close spontaneously. The great majority of children should have the ductus ligated between 7 and 10 years of age.

Coarctation of the Aorta in Children

There are now good prospects of correcting this curious anomaly by surgical resection of the aortic stricture. Unfor-

FIG. 1.—Teleradiograph showing the characteristic heart outline of a patent ductus in a youth aged 18. The heart size is within normal limits, but the pulmonary artery, which makes a prominent bulge on the left border between the aortic knuckle above and the ventricular mass below, is enlarged. There is increased vascularity of the lung fields. The presence of a patent ductus was confirmed at operation.

FIG. 2.—Teleradiograph of an enlarged heart in a child aged 4, with greatly increased vascularity of the lungs. The branches of the pulmonary artery are enlarged, but the pulmonary arc itself is not prominent. Patent ductus arteriosus confirmed at operation.

to the risks associated with complete surgical division of the ductus.

During the past five years 40 patients with persistent patency of the ductus have been under my personal observation (Gilchrist, 1946). In four the pulmonary artery was infected. Three of these came to operation. Only one, a girl of 6 years of age, survived. She made a prompt and brilliant recovery after an illness of six months' duration. This child is in perfect health a year after surgical ligation. Two patients died as a result of massive pulmonary collapse, each on the third day after operation. The fourth patient, following an illness of thirteen months' duration, died without operation ten days after the diagnosis was first made. Of 33 cases of subacute bacterial endarteritis collected by Shapiro and Keys (1943) surgical ligation of the ductus was completely successful in 20. Tubbs (1944) has reported recovery in 6 of 9 infected patients.

Among 16 non-infected patients, submitted to surgery in reasonably good health, we have had two deaths—one from

tunately the defect, though easy of diagnosis, commonly passes undetected in childhood. Eisenberg (1938), reporting the clinical recognition of coarctation in three children, was able to find in the literature only 15 examples under the age of 14, as compared with accounts of 114 adults. It is with the object of emphasizing its clinical recognition in early life that I record four cases, seen during the past six months, in which this flaw produced characteristic physical signs (see Table).

In the adult, as is well known, the constriction commonly situated distal to the origin of the left subclavian artery is accompanied by high blood pressure in the arm, neck, and head, and low pressure in the arteries, distal to the obstruction. Dilated pulsatile scapular and other arteries frequently visible on the chest wall circumvent the aortic obstruction, empty into the intercostals, in which blood-flow is reversed, and thereby provide anastomotic channels sufficient to meet the needs of the tissues distal to the coarctation. With the passage of time hypertensive symptoms commonly develop, the heart enlarges, the proximal aorta dilates, aortic incompetence results, and death occurs from congestive heart failure, cerebral haemor-

Coarctation of the Aorta in Children

Case No.	Sex and Age (Years)	Weight (lb.)	Height (in.)	Femoral Pulsation	Scapular Pulsation	Blood Pressure		Rib Notching	Remarks
						Arm	Leg		
1 (a)	M 8½	55 (26.3 kg)	52 (132 cm)	Absent	Present	114/74	Undetectable	Present	A rheumatic child. Frank mitral stenosis now present. Active boy, plays games vigorously.
1 (b)	M 8	77 (34.9 kg)	59 (150 cm)		"	140/96	90?		
2	M 8	61 (27.7 kg)	51½ (130.8 cm)		Absent	152/86	Undetectable	Absent	Very active, climbs trees, swings wood. Prominent carotid pulse. Coexistent patent ductus. No complaints. "Unusual pulsation in the neck since a baby."
3	F 12	Thin	Tall	Very feeble	"	173/80	110/94	Very slight	Tires easily, but able for school. A lively, active boy.
4	M 5	49 (22.2 kg)	44 (112 cm)			146/94	90/70	Present	

All four children had harsh left basal systolic murmurs. An interval of 3½ years separated the two examinations in Case 1. The leg blood pressures were recorded from the right popliteal artery. The arm pressures were noted in each arm, the figures from the right side being recorded in this table.

rhage, infective endarteritis, or aortic rupture, usually before age 45 is reached. The radiological examination depicts left ventricular hypertrophy, an absent aortic knuckle, and notching of the ribs as a result of the enlarged and tortuous intercostal arteries (Fig 3). Even with the adult in the left oblique position it is seldom that radiology can demonstrate the site of the actual coarctation (Brown, 1939). Fig 4, a skiagram from a man aged 49, is therefore exceptional. In it the aortic constriction is clearly outlined as a result of degenerative changes in the vessel wall. Intravenous diodrast may prove helpful to the surgeon in the future, as by this means the nature and site of the coarctation may perhaps be determined with accuracy (Nicolson 1940).

As aortic coarctation is generally symptomless in childhood it is a condition found only by making a thorough examination

more abundant blood supply the right arm may exceed the left in size (Schwartz and Greene, 1942). If coarctation of the aorta is to be recognized at the most opportune time—that is, in childhood when the prospects of surgical help are optimal—it is worth while to cultivate the habit of palpation of the femoral arteries in the groins, just as palpation of the apex

FIG 3—Teleradiograph depicting the typical features of coarctation of the aorta in an adult—a man aged 49. The noteworthy feature is the combination of absence of the aortic knuckle, left ventricular hypertrophy, and the presence of notches on the lower edges of several ribs.

Suggestive clues as to its presence are (1) a left basal systolic murmur—often called a "pulmonary systolic"—perhaps as well heard in the left interscapular region as in front of the chest, (2) bounding neck vessels; and (3) a raised brachial blood pressure. Confirmation of the presence of coarctation can readily be obtained by femoral palpation—the feeble or absent pulse in the groin, and the almost negligible pulse pressure in the popliteal artery with distant sounds when the blood-pressure cuff is applied immediately above the knee, being observations of the greatest significance. Similarly, more frequent blood-pressure readings in childhood will be the means of detecting coarctation at an earlier age. If the standard cuff is too large, overlapping at the shoulder or elbow, it is only necessary to fold it in half, so as to reduce its width, before its application to the child's arm. Reliable readings can then be obtained simply and accurately. Rarely, the coarctation is immediately proximal to the origin of the left subclavian artery. Hypertension is then confined to the right arm. As a result of the

FIG 4—Left oblique view of the heart and aorta of the same patient as Fig 3. The arrows indicate the upper and outer limits of the aortic arch and descending aorta. The arrow marked "C" indicates the site of the aortic constriction. The aorta proximal to the constriction is dense and dilated, distal to it the aorta is less dense, narrow, and tortuous. The esophagus is outlined with barium.

heart, neck, or abdomen forms part of the routine examination of the child. By this means J. W. Brown (personal communication) has recognized coarctation in a child of 2 years of age.

Of the present series all four children had harsh left basal systolic murmurs without detectable thrills. A diastolic aortic murmur was not heard, though regurgitation at the aortic valve is a common finding even in young adults (Perlman, 1944). Similarly, careful search revealed anastomotic vessels coursing over the scapulae in only one patient (Case 1)—a further contrast to a sign common in the adult. The radiological appearances are less distinctive in the child. Considerable cardiac enlargement was present in only one of my four patients (Case 4, Fig 5). Rib marking, virtually a pathognomonic sign in the adult, may be absent. The youngest child in this series showed definite "scalloping" of the lower edges of several ribs at age 5, another at age 8 had none (Case 2, Fig 6),

and the eldest of the series at age 12 had only the slightest indentations, easily overlooked had not the clinical examination already established the diagnosis. In this girl the coarctation was complicated by the presence of a patent ductus. None of the children had symptoms related to hypertension or to intermittent claudication. All were active and outwardly well, though one was a rheumatic child (Case 1) with a well-marked mitral stenosis in addition to the aortic coarctation.

Resection of the Coarctation

Crafoord and Nylin (1945) and Gross and Hufnagel (1945), working independently, now report their respective techniques for resection of the constricted segment of the aorta, which is then reconstructed by a continuous everting silk suture drawing intima to intima. This type of end-to-end anastomosis has proved eminently satisfactory. A year after the aortic repair Crafoord's two patients—aged 12 and 27 years—are in excellent health, with blood-pressure readings in normal proportions between the arms and legs. One of the two patients on whom Gross practised resection of the aortic stricture died. As soon as the clamps were removed from the aorta and the enormous

local infection the ultimate production of stenosis is as unlikely as aneurysm formation at the site of the arterial wound. Preliminary reports would indicate that the risks are worth taking—at least, when the arteries are young and resilient and the proximal aorta is unencumbered by atheroma, local calcium deposition, or diffuse degenerative changes.

The Cyanosed Child

In the presence of persisting cyanosis an exact anatomical diagnosis is more difficult than in the acyanotic group, the cardiac defects more often multiple, and the child delicate fragile, and susceptible to infection. In offering a palliative surgical procedure Blalock and Taussig (1945) have made a bold approach to the problem of treatment. By so reconstructing the circulation as to ensure the delivery of a greater volume of blood to the lungs aeration can be enhanced. Impressed by the importance of a diminution in pulmonary blood-flow as a cause of cyanosis in congenital heart disease, those authors report their results in three children, each handicapped by a high grade of Fallot's tetralogy, in whom a major artery, the innominate or subclavian, was anastomosed with the right or left branch of the pulmonary artery. In the tetralogy cyanosis is partly due

FIG 5.—Teleradiograph showing coarctation of the aorta in a boy aged 5 (Case 4). Cardiac hypertrophy and the absent aortic knuckle are striking features. Definite notches on the lower edges of several ribs—e.g., the 7th left and 7th, 8th, and 9th right.

FIG 6.—Teleradiograph showing coarctation of the aorta in a boy aged 8 (Case 2). Rib-notching is not evident in this patient; cardiac enlargement is less prominent than in Case 4 (Fig. 5). The aortic knuckle is visible but reduced in size.

vascular bed was in consequence thrown open, the child's heart "suddenly went into uncontrollable dilatation." The second patient reported by Gross—a 12-year-old girl—had the aortic clamps gradually released without incident. Before resection of the coarctation her brachial pressure lay between 215 and 190, with unobtainable readings in the legs. After repair of the aorta the systolic pressure in the arms was 140 and in the legs 145.

In the skilled hands of the thoracic surgeon this operation should not prove any more formidable than the procedure adopted for ligation of the ductus. Experimentally, a large artery such as the aorta heals firmly, intramural clotting does not give rise to difficulty, and Gross and Hufnagel (1945) point out that end-to-end reconstruction of the vessel does not lead to mechanical stenosis, indeed, in the animal the slight eversion of the walls tends to enlarge the internal diameter of the aortic tube at the point of union. Just as in the blind ends of the ligated ductus a smooth channel devoid of crypts is soon formed, so also the reconstituted aorta is lined by a continuous layer of endothelium and the walls heal firmly. In the absence of any

to the septal defect and partly to pulmonary stenosis. By the surgical production of an artificial ductus the stenosis is bypassed and the volume of blood which reaches the lungs for aeration is greatly increased. As the septal defect persists, with consequent mixture of venous and arterial blood, it is therefore impossible to bring the oxygen saturation of the arterial blood to normal, but the presence of the artificial fistula may permit of sufficient oxygenation to abolish "visible" cyanosis. Clinical improvement in the children has been striking, with distinct lessening of the cyanosis, a decrease in dyspnoea, and an increased tolerance for exercise. Blalock and Taussig emphasize the importance of a full investigation in order to determine as accurately as possible the anatomical lesion. When cyanosis arises from causes other than diminished pulmonary flow the construction of an artificial ductus will not be helpful.

As might be anticipated, the heart enlarges after this operation, the diastolic pressure falls, and the circulatory load is increased. It is therefore possible that benefit may be only temporary, congestive heart failure or bacterial endarteritis of the pulmonary artery being the main danger. As a palliative

procedure this operation has its justifications, but it is questionable if it will appreciably increase life expectancy. It is yet too early to form a final judgment. Further reports on the progress of these children will be awaited with interest.

Summary

Surgery can obliterate the patent ductus arteriosus and eradicate the congenital stenosis of the distal aortic arch known as coarctation of the aorta. The clinical diagnosis of these defects is discussed. The diagnosis of coarctation of the aorta is missed repeatedly in childhood by a failure to palpate the groins as a routine procedure. Feeble or absent femoral pulses make a characteristic finding. An account is given of four children in whom this defect was observed. Diagnosis of these congenital flaws within the first ten years of life is important if full advantage is to be taken of current surgical procedures designed for their correction.

RESISTANT ANAEMIA

A NOTE ON THE DIFFERENTIAL DIAGNOSIS OF PER- NICIOUS ANAEMIA AND FAMILIAL ACHOLURIC JAUNDICE

BY

A. H. DOUTHWAITE, M.D., F.R.C.P.
 Physician to Guy's Hospital

AND

R. L. WATERFIELD, M.B., M.R.C.P.
 Haematologist to Guy's Hospital

The purpose of this communication is to draw attention to the not uncommon error of confounding familial acholuric jaundice (F.A.J.) with pernicious anaemia (P.A.), and to show how that mistake may arise and how it can be avoided. Acholuric jaundice is usually regarded as a rare condition, but we are inclined to think that its supposed rarity is largely due to its being frequently overlooked. During the last fourteen months we have seen no fewer than nine previously undiagnosed cases of acholuric jaundice, each one belonging to a separate family. They were, in fact, numerically in excess of the new cases of true pernicious anaemia with severe anaemia seen during the same period. Among such cases of pernicious anaemia we do not include those suffering from a greater or lesser degree of P.A.-factor deficiency secondary to some other disease such as sprue, carcinoma of the stomach, or liver cirrhosis, nor do we include cases suffering primarily from symptoms of subacute combined degeneration of the cord with a slight or negligible degree of anaemia. Now, of our nine cases of acholuric jaundice no fewer than four had been diagnosed as pernicious anaemia and treated as such for periods up to as long as five years. In a much larger series of cases seen prior to 1940 this same mistake was noted in a somewhat similar proportion, but owing to the loss of part of the card index during the war the details of that series are not available. The present note will therefore refer only to cases seen since October, 1944. Though the series is a small one the figures we have just given clearly show that the disease acholuric jaundice and the mistake to which we refer are common enough to merit attention.

The Clinical Picture

Clinically familial acholuric jaundice, with its anaemia and icterus, bears a close resemblance to pernicious anaemia.

Jaundice.—In F.A.J. there is usually slight or moderate icterus, but it may be very marked, and occasionally it is absent. In the latter case a history of one or more previous attacks of yellowness may be obtained. In this connexion one must bear in mind the frequency with which pigment stones occur in F.A.J., giving rise to attacks of gall-stone colic or obstructive jaundice. One of our cases was admitted to hospital deeply yellow as a result of biliary obstruction, and it was only during the routine examination of the blood picture that the underlying cause of the condition was shown to be F.A.J. In another case a cholecystectomy had been performed ten years before on account of two attacks of jaundice and biliary colic, but the significance of the pigment stones which were found was not appreciated.

Splenomegaly.—Sometimes a gross splenomegaly will exclude P.A. and indicate the true diagnosis. But frequently the spleen is not palpable in F.A.J., and very often it is no more easily palpable than in many cases of P.A. In one of our cases showing all the other characteristics of F.A.J. there was no increase in the size of the organ when it was examined at operation.

Ulceration of the Legs.—When there is chronic ulceration of the legs or a history of such ulceration, in association with anaemia the diagnosis is beyond doubt, unfortunately, leg ulcers probably occur in less than 20% of the patients though in this short series it was seen in over 40%. The ulcers usually occur at a higher level than those associated with varicose veins, though sometimes they are found round the ankles over the malleoli. Often affecting the middle of the leg, they may lie anteriorly or posteriorly, and tend to spread slowly but remorselessly. They are usually intensely painful and are resistant to all local treatment, although they tend to heal during prolonged rest in bed. Splenectomy, which abolishes all the symptoms of F.A.J. results in the healing of the ulcers in about six weeks.

Family History.—A family history of anaemia, and more particularly of jaundice or of ulceration of the legs, is very suggestive. Yet often one can obtain no such history even after diligent questioning, while, on the other hand, one must avoid being misled by the not uncommon story that "anaemia runs in the family" and by the fact that occasionally patients with P.A. give a family history in which jaundice as well as anaemia plays a prominent part. One of our patients told us that her brother had died of leukaemia, and another that her mother and brother had succumbed to splenic anaemia. Investigation made it clear that in both these families the deaths had been due to F.A.J. Five out of our nine cases gave a relevant family history.

Periodicity.—Another point which may help in the clinical diagnosis is the story of the periodic nature of the attacks of anaemia and yellowness. This seldom happens in P.A. unless the patient has received intermittent treatment with liver. But so many of the cases of F.A.J. which one sees are in their first "attack" and give no history of previous ones.

Age.—It must be emphasized that the signs and symptoms of F.A.J. often remain latent till late in life. Thus five of our patients were over 50 when their first symptoms appeared, three were over 60, and one was over 70.

Alimentary and Nervous Signs.—Other aids to the clinical differential diagnosis consist in the presence or absence of the signs and symptoms referable to the alimentary and central nervous systems which are so frequently present in P.A. But whereas the history or presence of such signs and symptoms when well marked is highly suggestive of P.A., their absence by no means excludes that disease. It must be remembered that glossitis occurs in many other conditions apart from P.A., and that "pins and needles" in the hands or feet, which is perhaps the commonest early symptom of subacute combined degeneration of the cord may be found in any severe anaemia presumably as the result of peripheral anaemia. It is worth noting, in this connexion, that "pins and needles" due to an anaemia *per se* is likely to be perfectly symmetrical in distribution, while a definite asymmetry, with the tingling more pronounced on one side than another, is more suggestive of an organic and presumably neurological lesion. It cannot be too strongly emphasized how important it is in every suspected case of P.A. to have a fractional test meal examination.

If any free acid is found it is absolutely certain that the case is not P.A.—at least, not one of the primary Addisonian type. On the other hand, the absence of free acid, though strongly suggestive of P.A., does not completely exclude F.A.J. Thus in the six of our cases in which it was practicable to carry out a test-meal examination there was an absence of free acid in two.

The Blood Picture

It is not only the clinical picture which may confuse the practitioner, for the haematological picture, at least in its elementary form, may be even more misleading. The reason for this is that most cases of F.A.J. have a high colour index. It is seldom much below unity, it is often well above unity, and it is occasionally higher than in any other disease. Unfortunately, a colour index definitely above unity is popularly regarded as pathognomonic of P.A. or of one of those rare macrocytic anaemias which differ from P.A. only in their failure to respond to liver.

For perhaps the majority of clinicians the blood picture as regards the red cells is complete if a red cell count and haemoglobin estimation are done. These two figures, together with their quotient the colour index, are all the information that is considered. The remarks of the pathologist as to the degree of anisocytosis, anisochromia, poikilocytosis, etc., tend to be regarded as little more than frills to lend some semblance of complexity to an otherwise simple report. A reticulocyte count and a measurement of the mean diameter of the red cells seem to be looked upon as a luxury barely worth the extra trouble. Yet it is chiefly upon these three pieces of information—the mean cell diameter and its relation to the colour index, the appearance of the red cells in stained films, and the reticulocyte count—that the successful differential diagnosis between F.A.J. and P.A. depends.

Colour Index and Mean Cell Diameter.—Whereas the colour index is usually high in both F.A.J. and P.A., the mean cell diameter is generally much increased in P.A. and much diminished in F.A.J. This apparent discrepancy—a high colour index with a small mean cell diameter—is one of the characteristic points in the blood picture of F.A.J.

Usually the mean cell diameter is smaller than in any other condition—often less than 6μ ; yet the colour index is around unity or even above it. Less commonly, the mean cell diameter is only slightly reduced, when the colour index will be well above unity. Finally, in rare cases the mean cell diameter is actually above normal, and then the colour index may reach extraordinarily high values. The reason for this is the spheroidal shape of the cells, which results in their surface area and volume being much larger in proportion to their diameter than is the case with normal red cells, with their comparatively thin disk-like figure. This sort of discrepancy is seen only in F.A.J. In P.A. one occasionally gets a discrepancy in the opposite direction—a large cell diameter with a low colour index—due to a post-haemorrhagic anaemia being superimposed on the macrocytosis. This will happen when there is some incidental cause of blood loss such as haemorrhoids, or when the thrombocytopenia associated with P.A. is sufficiently developed to produce a haemorrhagic purpura.

The Appearance of the Red Cells in Stained Films.—Irregularities in the size, staining, and shape of the red cells tend to be well marked in the majority of severe anaemias. They are absent or but slightly noticeable only in those severe anaemias that are due to an aplasia of the bone marrow or which are associated with toxic or infective processes where there is presumably some general depression of bone-marrow function. Now, while it is fully realized that the extent to which these abnormalities of the red cells are developed gives a rough indication of the degree of marrow activity, it is not usually appreciated that a more subtle analysis of these abnormalities will often supply us with information of the greatest diagnostic value. In particular it is by close attention to the detailed appearance of the red cells in stained films that one most readily avoids the mistake of muddling F.A.J. with P.A. In the majority of anaemias where there is gross irregularity in the size of the red cells there is also great irregularity in their shape, and this is especially true in P.A. But in F.A.J. one of the most striking features is that although the cells have an enormous range in size they are extraordinarily uniform in

shape, being almost perfectly circular disks: there is, in fact, gross anisocytosis without poikilocytosis. Again, irregularity in the depth of staining of the cells, "anisochromia," is by no means uncommon in severe anaemias. Usually it is what one might call "irregular" in type—that is to say, many of the large cells are pale and many are dark—while the same is true of the small cells. In a typical case of P.A. there is usually little or no anisochromia, all the cells being fairly completely and uniformly filled with haemoglobin. In severe hypochromic anaemias there is again little or no anisochromia; but here the cells are very deficient in haemoglobin and appear uniformly pale. However, in cases of hypochromic anaemia and P.A. under treatment with iron and liver respectively, when the haemoglobin production tends to lag behind the cell formation, the anisochromia often becomes very striking. If there is any tendency towards regularity in the anisochromia of P.A. under treatment, it is that the larger cells tend to be more completely filled with haemoglobin and to appear pinker than the smaller cells. But in F.A.J. the picture is quite different: the anisocytosis and anisochromia are of striking regularity, the great majority of the small cells staining deeply and the large cells palely. *There is no other condition in which this happens;* and usually the appearance is so remarkable that one look at the stained film without any other examination, haematological or clinical, is sufficient to make one extremely suspicious of the correct diagnosis.

Reticulocytes, Stippled Cells, and Diffuse Basophilia.—Although a gross reticulocytosis is in no sense pathognomonic of F.A.J., it is nevertheless a feature which distinguishes absolutely between that disease and P.A. In a severe untreated case of P.A. the reticulocytes are usually not increased above the normal 1 to 1½% of the total red cell count, and they seldom if ever exceed 2 or 3%. In a case of F.A.J. in which the anaemia is severe there is always a gross reticulocytosis: it is usually at least 15 to 20%, and often 40 to 50% or even much higher. One must of course beware of the severe case of P.A. which has recently received an injection of liver, so often administered before the diagnosis is established. Although a high reticulocytosis may occur in any of the other haemolytic anaemias, such as lead-poisoning, and to a less extent after an acute haemorrhage, in hypochromic anaemia under treatment with iron, in certain types of leukaemia, and in leuco-erythroblastic anaemia the other haematological characteristics of F.A.J. will be missing, while features peculiar to these conditions will usually be present.

A small percentage of stippled cells are usually to be seen in P.A.; but in F.A.J., though there is a gross reticulocytosis, few if any of these cells appear as stippled cells with Romanovsky stains. Many of the reticulocytes in F.A.J. appear bluish (diffusely basophilic) in the Leishman-stained films. This supplies another feature which may help in distinguishing the disease from P.A. When diffuse basophilia is well developed in F.A.J. as many as 10 or 20% of the cells may have a bluish tint, whereas in P.A. the figure never reaches 1% of the total cell count.

Nucleated Red Cells.—Nucleated red cells are usually present in both P.A. and F.A.J., and may occasionally reach high figures; but the type of nucleated cell is very different in the two conditions. In P.A. these cells are of all degrees of immaturity; in F.A.J. the vast majority of them are late-type cells with solid-looking, structureless nuclei. Moreover, these pyknotic nuclei frequently assume bizarre shapes not often seen in other diseases, being double-lobed, triple-lobed, or even mulberry-like in appearance.

The White Cells.—In F.A.J., when the anaemia is marked, there is usually a polymorphonuclear leucocytosis with a left shift, both of which may be considerable. In P.A., on the other hand, there is nearly always some degree of leucopenia due to reduction in the polymorphonuclears; while among the granulocytes which remain there are not only immature cells, which may include myelocytes and even metamyeloblasts, but also some very large polymorphonuclears with highly complicated lobulation of their nuclei: a shift simultaneously both to left and to right.

In Table I we have summarized the main differences in the blood pictures of F.A.J. and P.A., and in Table II the clinical features of our nine cases of F.A.J.

TABLE I.—Main Differences between the Blood Picture of Acholuric Jaundice and that of Pernicious Anaemia

	F. A. J.	P. A.
Colour index	High	High
Mean cell diameter	Low	High
Anisocytosis	Marked	Marked
Poikilocytosis	Absent	Marked
Anisochromia	Marked and irregular	Slight
Stippling	Absent	Moderate
Diffuse basophilia	May be gross	Moderate
Reticulocytosis	Extreme	Absent
Nucleated red cells	Late type	All types
White cells	Leucocytes	Leucopenia

It must be realized that the above remarks apply only to cases of F.A.J. and P.A. which are in an active phase of the disease. In cases of F.A.J. with but a mild degree of anaemia, or which are discovered during the routine examination of an acholuric family, the above characteristics will naturally be less well developed; but even in such cases some or all of them are generally fairly obvious.

Fragility.—So far we have refrained from any reference to fragility of the red cells because we have been concerned only with the more elementary points in the diagnosis. We maintain that the determination of the fragility of the red cells,

ated with clinically recognizable jaundice, demands painstaking clinical and laboratory work. The ultimate justification for this labour must be the availability of successful treatment. This is presented in splenectomy. In skilled hands the operation is not hazardous, for the spleen is never bound down by adhesions as in splenic anaemia. Although it is desirable by means of blood transfusion to raise the haemoglobin to a reasonable level before operation, it is sometimes impracticable to achieve this ideal owing to the rapidity of the red cell destruction going on in the body. In such cases, rather than delay too long it is better to operate at a comparatively low haemoglobin level and to give a further transfusion of blood immediately after the operation. It is remarkable how rapidly in most cases the haemoglobin rises when once the spleen is removed. In one of our cases a two-pint (1.14 l.) transfusion of fresh blood raised the haemoglobin only from 40% to 45%; splenectomy was then performed, being followed immediately by the giving of two further pints of blood, and within 24 hours the haemoglobin had risen to 70%.

Summary

The frequency with which familial acholuric jaundice is wrongly diagnosed and treated as pernicious anaemia is emphasized.

The commonest causes of this mistake have been found to be: (1) An unfounded belief in the diagnostic value of the colour index.

TABLE II.—Chief Clinical Features of 9 Cases of Acholuric Jaundice

Case	Sex and Age	Anaemia (Hb)	Jaundice	Leg Ulcer	Splenomegaly	Pigment Stones	Family History	Previous Diagnosis
N. M.	F. 48	56%	—	—	Spleen not palpable, but large at operation	—	—	N.I.
R. B.	F. 19	62%	Obstructive J. — +	—	Slight	—	—	Obstructive jaundice
J. B.	F. 22	30%	Slight	—	Spleen not large at operation	—	—	Obstructive anaemia
M. G. B.	F. 41	74%	—	—	Slight	—	—	P.A.
E. H.	F. 63	40%	Slight	—	—	—	—	P.A.
L. D.	M. 53	56%	Slight	—	++	—	—	N.I.
H. D.	M. 52	38%	—	—	Slight	—	—	N.I.
W. G.	M. 73	42%	—	—	Slight	—	—	P.A.
E. R.	F. 68	35%	Slight	—	Slight	—	—	P.A.

unless carried out by someone who has considerable experience of the test, is often valueless and not infrequently misleading. It is not always realized that in a considerable proportion of the cases of F.A.J. the fragility of the red cells is only very slightly increased above the upper limit of normal. In one of our nine cases there was a previous report from a reputable laboratory that the fragility of the red cells was normal; while in another the departure from the normal, though recognized, was so slight that its significance was overlooked. As examples of the variability of the fragility from one case to another the following figures from two of our series are illuminating.

TABLE III.—Showing Different Degrees of Fragility of Red Cells of Fully Oxygenated Heparinized Venous Blood in 2 Cases of F.A.J. compared with the Normal

% NaCl	H. A.	R. B.	Normal
	% Haemolysis	% Haemolysis	% Haemolysis
0.30	100	100	100
0.35	100	100	100 approx.
0.40	100	100 approx	60
0.42	100 approx	—	15
0.44	100 approx	50	12
0.46	80	20	10
0.48	60	3	Trace
0.50	40	Trace	Nil
0.52	30	Trace	Nil
0.55	20	? Trace	Nil
0.60	10	Nil	Nil
0.65	5	Nil	Nil
0.70	1	Nil	Nil
0.75	—	Nil	Nil
0.80	—	Nil	Nil

In a satisfactory fragility test it is necessary (1) to make up very accurate solutions of the various saline dilutions; (2) to make certain that the blood is fully oxygenated before introducing it into the saline solutions; and (3) always to carry out a quantitative estimation of the percentage of haemolysis in each saline dilution.

Treatment

From the foregoing description it will be seen that the diagnosis of familial acholuric jaundice, a disease so often unassoci-

(2) Ignorance of the fact that free acid in the gastric juice excludes pernicious anaemia (3) Failure to appreciate the extreme importance of detailed blood examination. (4) Attribution of natural remissions to the effect of liver administration and of relapses to faulty liver preparations (5) Failure to grasp the importance of chronic ulceration of the legs and anaemia as signs of familial acholuric jaundice.

SPLenic CYSTS: WITH A REPORT OF A CASE

BY

MICHAEL HARMER, M.B., F.R.C.S.

Surgical Specialist, R.A.F.V.R.

AND

J. A. CHALMERS, M.D., M.R.C.O.G., F.R.C.S.E.D.

Lately Gynaecological Specialist, R.A.F.V.R.

Splenic cysts are rare. All writers on this subject begin their articles with these words and go on to quote figures given by Fowler (1940) in analysing 137 cases of non-parasitic splenic cysts.

Andral (quoted by Fowler, 1940) in 1829 described the first splenic cyst, which was found at necropsy and proved to be a dermoid. In 1880 Pean (Fowler, 1940) performed the first splenectomy for a cyst, and in 1906 the first series of 36 cases was described by Powers (Fowler, 1940). Since Fowler's review the interest of surgeons has been aroused, for cases have been recorded in fair numbers. By 1942 McClure and Altemeier had raised the total to 149, and later in that year Gallagher and Mossberger described the 155th non-parasitic cyst. Up to the end of 1944 seven further examples had been listed, and our case would appear, therefore, to be the 163rd.

That the condition is indeed uncommon can be seen by reference to the standard textbooks of surgery and pathology, which have little or nothing to say on the subject. Like most rarities it is of course probable that many cases went unrecorded until more recent years. A search through the literature reveals a willingness on the part of the authors to compose elaborate classifications of these few cases, which discourages us from attempting anything similar.

It is certainly expedient to distinguish parasitic (hydatid) from non-parasitic cysts in the first instance. The former are said to be at least twice as common as the latter. Arce (1941) of Buenos Aires found the spleen affected by hydatid cysts in 3% of his cases, and Dew (1928) that 2% of all hydatids were in the spleen. It is, we think, reasonable to regard the non-parasitic cysts as "true" or "false" according to whether there is an endothelial (or epithelial) lining or merely a connective-tissue lining. It is on the basis of this distinction that Fowler records the ratio of true to false as 1:4; or, as those who prefer percentages would say, only 20% of non-parasitic cysts are true and 80% are false. This distinction, however, may be liable to error, for in certain cases an endothelial layer may disappear as a result of pressure from, for example, haemorrhage; while in others a lining may even be acquired by metaplasia of connective-tissue elements. How often this may happen it is impossible to say, but that it does occur is suggested by the fact that some areas of certain of the cysts described show an epithelial lining and other areas only connective tissue. In this connexion Gallagher and Mossberger (1942) point out that the terminal findings may mislead as to aetiology.

Discussion

True cysts include dermoids and epidermoids and those lined by endothelium. Although it is difficult to explain the presence of ectoderm in the spleen, this is the only source of these tumours. A possible explanation is that they are derived from a primitive totipotential cell capable of producing any of the three layers, such as is postulated to explain the ovarian and testicular dermoids.

Endothelium-lined cysts are easier of explanation and can be accounted for as haemangiomas, lymphangiomas, and serous cysts arising possibly from inclusion of peritoneal cells, together with the multiple cysts associated with polycystic disease of other organs. Lubarsch (quoted by Fowler, 1940) considers that some of the serous cysts may be neoplasms arising from anlagen of lymphatic endothelium.

False cysts are usually large and single, and contain blood or blood-stained serous fluid and often cholesterol crystals. They tend to be situated at either pole of the spleen, with normal splenic tissue elsewhere, and part of the cyst wall may be formed by thinned-out spleen, though Fowler describes cartilage and smooth muscle occurring in the walls. In places the wall may be fibrous. Gallagher and Mossberger (1942) describe a pedunculated calcified cyst attached to the lower pole of the spleen surrounded by normal tissue, and McClure and Altmeier (1942) have observed the occurrence of torsion of the pedicle as a rare event. The cause of false cysts is considered to be trauma or infection, or degeneration in an infarcted area. Malaria is mentioned as a predisposing cause, and we have recently been informed by an R.A.M.C. colleague that in West African natives, in whom malaria is almost universal, splenic cysts are not infrequently found at necropsy. Syphilis and the other causes of splenomegaly may render the spleen liable to exposure to trauma, and if this is associated also with toxæmia it will make haemorrhage all the more probable. The suggestion that splenic congestion occurs during menstruation (Denneen, 1942) and that intrasplenic haemorrhage and cyst formation are therefore more likely in women during the phase of active sexual life is dismissed by Fowler, and there is nothing to support this belief in the textbooks of gynaecological physiology. Seven per cent. of cysts occur during pregnancy (Fowler), but this has probably been a coincidental finding, the presence of the cyst being observed when the uterine fundus begins to encroach upon the upper abdomen. They occur at all ages, but particularly in young adults, and women are rather more often affected than men.

Diagnosis.—When small a cyst will give rise to no symptoms, and when larger it will cause pressure symptoms and very little else; or it will be noticed by the patient or others. Milroy Paul (1943) says "the diagnosis . . . has rarely been made," and Fowler himself uses the same phrase. It is therefore encouraging to read Sweet's (1943) opinion that "large cysts, however, present a clinical picture so characteristic that the diagnosis can be readily made," and to record that in the case to be described the diagnosis was in fact made by one of us (J. A. C.), though the co-author and a considerable number of other medical men scorned his suggestion.

Dyspepsia, a dragging pain, and inability to eat a large meal owing to compression of the stomach are the chief complaints. If inflammation exists pain will be more severe. The past history may be of help in cases of malaria, syphilis, or trauma. Trauma as a cause of splenic rupture and also as a factor in the production of pseudo-pancreatic cyst is well known. But it is easy to visualize an injury which will cause intrasplenic haemorrhage only and result later in the formation of a splenic cyst. Hydatid disease should be looked for in members of stock-breeding communities and its presence confirmed by Casoni's or other specific tests.

If the cyst occupies only a part of the spleen the rest may be palpable, and this will aid in diagnosis. But if the whole organ is involved, or nearly so, it will be necessary to differentiate cysts of the pancreas, left lobe of liver, omentum, kidney, or ovary. The last should be easy, for a spleen seldom reaches the pelvis and an ovarian cyst seldom gets completely out of it, so that if the cyst originates in the spleen one should be able to "get below it." One can usually "get above" a pancreatic cyst, which should be strictly a midline structure, whereas a splenic cyst, unless pedunculated, is never completely below the costal margin and extends across the midline only if it is of considerable size. A palpable notch would be of diagnostic importance, but this has rarely been noted.

Aspiration of the cyst with the finding of cholesterol crystals is cited by Denneen (1942) as an aid to diagnosis, but the dangers inherent in this procedure should the cyst be echinococcal or an aneurysm would seem to weigh heavily against its advantages.

Radiography.—Elkeles and James (1943) state that "in the few cases in which a correct diagnosis was made prior to operation, x-ray examination was the determining factor," and certainly it has much help to offer. Where calcification has occurred it is clearly almost diagnostic, for a calcified cystic shadow in the left upper quadrant of the abdomen is likely to be either a splenic cyst or an aneurysm of the splenic artery, and the latter can be excluded reasonably easily by auscultation. This calcification often takes place in spite of the youth of a patient and a short history. Snoke (1943) quotes cases at the ages of 18, 25, 44, 52, and 60. In the absence of calcification a soft-tissue swelling which obliterates the psoas shadow, raising of the left diaphragm, and spreading of the lower ribs are seen. Sweet (1943) draws attention to the fact that the swelling, though generally rounded, often has a pointed lowest extremity where solid splenic tissue remains.

A barium meal will show the stomach to be pushed across to the right and compressed backwards, and the splenic flexure to be displaced downwards and to the right according to the size of the tumour. Intravenous and retrograde pyelograms have shown the kidney to be pushed downwards (cases quoted by Fowler, 1940; Roberson, 1940; Elkeles and James, 1943; and Sweet, 1943) or upwards (cases quoted by Shawan, 1933, and Snoke, 1943).

Treatment.—There is no doubt that splenectomy is the proper treatment unless prevented by the presence of dense adhesions. Fowler puts the mortality at 4%. Enucleation has been practised on occasion, but there is a danger of haemorrhage from this procedure. Marsupialization and incision and drainage are apt to be followed by fistula and amyloid disease, not only in hydatid cysts but in non-parasitic ones as well (Arce, 1941). There seems little doubt that emptying the cyst makes removal easier, provided infection and hydatid are excluded.

Case History

A girl aged 24, a member of the W.A.A.F., unmarried, was found at a routine medical examination to have a huge swelling in the upper abdomen. She had always been "plump," but the swelling had been present to her knowledge for only 10 years. A vague story of injury to the lower left ribs four years previously was dismissed as probably of no importance. The swelling had gradually increased in size and had given rise to dragging abdominal pain only during the last few months, in which period she had noticed that she had had to be content with small meals, as she readily became "blown out." Questioning failed to elicit any other symptoms incriminating the digestive, urinary, or genital systems. She had not noticed any shortness of breath.

Examination was equally unhelpful except for the swelling itself. This was well defined and clearly cystic, and occupied the whole of

the epigastrium. It lay slightly obliquely across the abdomen, the left side being lower than the right, but the axis was horizontal rather than vertical. Below, it reached to the level of the umbilicus, but was not palpable in the loin or left renal angle. No notch was felt. Its lower edge was well defined, and it was agreed that the cyst could be moved slightly up and down but not from side to side. It was dull to percussion, silent on auscultation, and displaced the gut downwards. The liver was not enlarged and no other abnormal physical signs were detected. A plain skiagram showed the shadow of a large soft-tissue swelling, and a barium swallow demonstrated that the stomach was pushed away to the right and also compressed backwards. Blood count and urine examinations were normal.

A diagnosis of pseudo-pancreatic cyst was made with a minority report in favour of splenic cyst as previously mentioned. It was considered that a renal origin for this swelling could be safely excluded.

Operation (Aug. 10, 1945: Air Vice-Marshal Stanford Cade).—It was decided to explore through a left paramedian incision, cutting across the rectus muscle to gain extra space if necessary. On opening the peritoneum a shining rounded tumour of a beautiful duck-egg blue was seen, and it was thought that the first diagnosis was correct. But further exploration showed this to be a large round area of fibrous cyst wall, the remainder of the tumour being typically plum-coloured splenic tissue, thinned out over the cyst and forming a margin of grossly normal spleen to the right and below and including the notch. The latter had not been palpable clinically because it lay beneath the right costal margin, so far did the spleen extend across the midline.

An incision was made through this thin fibrous area and about 3½ litres of fluid removed by sucker. This fluid was brownish, opalescent, and of the consistency of dish-water. The cyst collapsed and, with the division of a few adhesions and the pedicle, was easily removed through the original incision. The peritoneal cavity was mopped dry and the wound closed without drainage. Convalescence was uneventful. Six weeks later a barium meal showed a stomach of normal size, shape, and position. The patient was symptomless and had returned to duty.

The Specimen.—The cyst, together with the fluid removed, weighed approximately 13 lb. (5.85 kg.). The wall was leathery, and it was easily distended again for the purpose of fixation, though not to its original size. The photograph indicates the present size, the cir-

cumference being 24 in. (60 cm.) in its long and 21½ in. (54 cm.) in its shorter axis. The fluid contained red blood cells and polymorphs, some degenerate but mostly recognizable. Numerous cholesterol crystals were seen and culture was sterile. In places the wall was purely fibrous and translucent; in others a layer of spleen about 1 cm. thick was stretched over it. The interior of this single cavity showed massive trabeculation and a considerable quantity of necrotic fibrous tissue adherent to the walls.

On section the "sandwich" effect of a layer of spleen enclosed between a thick fibrous capsule on the outer side and a less thick fibrous lining on the inner side was well seen. The latter was not limited by any specialized epithelial or endothelial cells. A section through "normal" splenic tissue taken from the anterior margin of the cyst showed increased fibrosis but no other abnormal change.

Summary

A case of false splenic cyst of considerable size in a young woman described.

The size of the cyst was out of all proportion to the symptoms.

A pre-operative diagnosis was made and the condition was successfully treated by splenectomy.

Skiagrams taken before operation showed compression and displacement of the stomach, which state of affairs had righted itself six weeks later.

The literature is reviewed and differential diagnosis considered.

The specimen has been accepted by the Royal College of Surgeons.

(NOTE.—Since going to press further sections have been cut and show that in places the cyst was lined by flattened endothelium. Patchy calcification was seen here and there. It is considered that these appearances are not inconsistent with the description of the cyst as "false.")

SIGNIFICANCE OF THE PREMENSTRUAL FEVER IN PULMONARY TUBERCULOSIS

BY

R. GRENVILLE-MATHERS, M.B., Ph.D., F.R.F.P.S.

Physician, Pendyffryn Hall Sanatorium, Penmaenmawr

In recent years pulmonary tuberculosis has been diagnosed by radiography, to a greater extent than ever before, at a stage when no abnormal physical signs are present. Once the diagnosis is made, the next step is to determine whether the disease is active or not. In many cases admitted to sanatoria investigation shows only healed scars. Serial skiagrams, however, reveal definitely whether the lesion is active or not, but these changes take some time to declare themselves. In 1921 Sir James Kingston Fowler wrote that "the temperature is the guide to the activity of the disease." But many cases which on admission to sanatoria appear to be afebrile, in that their temperature never rises above 98.4° F., prove later to have a natural maximum temperature of only 98° F. or even 97.8° F., so that the early readings really represent a mild degree of pyrexia.

The Present Investigation

In this connexion there arises a question of great importance—namely, the significance of the premenstrual temperature in women. If the temperature increases, does the increase indicate tuberculous activity, or can it be disregarded in considering increases in patients' exercise? In an attempt to elucidate this problem 15 normal healthy young women were persuaded to take their temperature as controls, both morning and evening, for ten minutes in the mouth, as is done in recording the patients' temperatures in this sanatorium. This was done for at least one whole menstrual cycle. Van de Velde (1904, 1929) first showed that in the normal woman the body temperature is relatively low during the first and relatively high during the second half of the menstrual cycle. Barton and Wiesner (1945) have confirmed, by taking the waking temperature, that a relatively high temperature is characteristic of the premenstrual phase, and that it persists after conception. Such a biphasic change was found in 13 of the 15 normal women studied, and the temperature reached a steady maximum beginning a few days before menstruation was due. The reactions were of three types. First, a rise in both the morning and the evening temperatures; secondly, a diminution in the daily variation, usually caused by a rise in the morning temperature; and, thirdly, a combination of these two changes—i.e., a rise in temperature as well as a diminution in the daily variation. The changes fell with almost equal incidence into these three groups. The average duration of this premenstrual change in the temperature was 5 days. The highest temperature reached was in no case above 99° F., and this occurred in only one instance. In 75% of cases the premenstrual temperature showed no readings above 98.4° F.

Of 50 women of child-bearing age with pulmonary tuberculosis premenstrual changes occurred in 43. The reactions were of the same three types as occurred in the controls, and the incidence of each type was the same. The average duration of these changes, however, was 9 days instead of 5, and in 53% the temperature reached was 99° F. or over. As soon as the menstrual flow started the temperature reverted to its previous character.

In 6 of these patients the characteristic changes were absent when a temporary increase of tuberculous activity occurred. During this exacerbation, shown either by a higher temperature recording or by a bigger variation in the morning and evening temperatures, the premenstrual phase invariably disappeared. When the toxæmia decreased the phase reappeared. Table I

TABLE I.—Showing Effects of Variation of Toxaemia (indicated by Periods grouped a, b, c) on the Premenstrual Phase

Case	Daily Intermenstrual Temperature Variation (° F.)		Duration of Premenstrual Change in Days	Temperature Variation during Premenstruum (° F.)	
	a.m.	p.m.		a.m.	p.m.
I	(a) 98.4	100.0	Nil	98.4	100.0
	(b) 97.4	98.2	9	98.0	98.4
	(a) 97.6	98.8	12	98.4	100.8

	(a) 98.0	99.0	7	98.0	98.8
	(b) 97.4	98.4			

records the daily variations in temperature and the premenstrual changes in these 6 cases, and shows how, at times when the temperature variations were greater owing to increased toxæmia, the premenstrual change disappeared. Martin (1943) has shown, by examining endometrial biopsies, that absence of a premenstrual variation in temperature is due to ovulation not having occurred. Tuberculosis is recognized as a cause of amenorrhoea, and it would appear that in the 6 tuberculous cases which did not show a premenstrual temperature change, once the toxæmia reached a certain level, there was a tendency to swamping of the endocrine changes, but without actual amenorrhoea ensuing.

Another of the 43 patients possessed charts, extending over a period of five years, showing an original premenstrual rise in temperature lasting for 14 days; now, when the degree of activity of the disease is much less, the rise lasts for only 5 days. In another patient there has been a gradual diminution in the duration of the premenstrual change and in the maximum temperature reached, until finally it has vanished completely.

Seven of the 50 patients showed no premenstrual change at any time. In one of these cases, with a temperature variation of 99 to 100.6° F., there was amenorrhoea. In the other 6 toxæmia was present but the temperature range was comparable to that of 5 patients who did show a reaction (Table II).

TABLE II.—Showing the Similarity in Temperature Range in Patients with, and without, a Premenstrual Variation

Case	Patients showing no Premenstrual Change		Patients with Similar Temperature Swing but showing Premenstrual Change				
	Daily Temperature Swing (° F.)		Daily Temperature Swing (° F.)		Duration of Change (days)	Premenstrual Temperature (° F.)	
	a.m.	p.m.	a m.	p.m.		a m.	p.m.
1	97.8	99.2	98.0	99.0	5	98.4	99.2
2	98.0	99.2	98.4	99.2	8	99.0	99.6
3	97.0	99.0	98.0	99.0	12	98.4	99.4
4	98.0	99.0	99.0	100.0	5	98.4	101.0
5	98.0	99.0	98.2	99.2	8	99.2	100.2

One woman had had amenorrhoea for five years. In spite of this a regular change in her temperature occurred every 28 days, lasting for 10 days. After spinal analgesia for an

appendicectomy she had one period lasting 2 days. This occurred on the day that her temperature was due to come down, and did so, just as it does in those women having a premenstrual change. A dilatation and curettage had been done four years previously, but unfortunately no microscopy was carried out at that time. Sharman (1944) investigated 883 cases of primary sterility and found that 5.3% had tuberculous endometritis; so it appears that subclinical tuberculosis of the female genital tract is a not uncommon cause of sterility. It would seem that in this case the endocrine changes associated with menstruation occurred, but it is surmised that the endometrium could not react to the hormonal stimulation.

The elucidation of the premenstrual change is not easy. Occasionally it is accompanied by some increase in the number of rales and crepitations which can be heard in the chest, and this would point to there being an increase in the activity of the disease. In 4 patients the day preceding menstruation was marked by a sudden extreme rise in temperature, the evening maximum being 1.6 to 2.6° higher than usual. This reaction bears a strong resemblance to a tuberculin reaction, and it would appear that in these patients there had been a sudden flooding of the blood stream with tubercle toxin.

The symptoms of which many women complain during the few days preceding menstruation are very similar to those of over-activity of the thyroid gland—e.g., irritability, sweating, tremor, and nausea. It appeared, therefore, as if the thyroid might be in some way implicated in this change. In an attempt to settle this point thiouracil was administered in 6 cases chosen from the above series as showing a reasonably constant monthly cycle. Thiouracil inhibits over-activity of the thyroid by preventing conversion of available iodine into the thyroid gland hormone (Franklin *et al.*, 1944; Rawson *et al.*, 1944). Thiouracil had been previously tried in the treatment of tuberculosis and found to have no effect. This was not unexpected, since estimations of basal metabolism in tuberculous patients generally show a normal standard figure independent of activity, extent, or type of lesion (Kayne *et al.*, 1939), but it was thought that the reduction in cardiac output brought about by thiouracil might be beneficial. The drug was given in a dosage of 0.6 g. daily, starting on the first day of temperature change. No noticeable change was produced, but it is known that in thyrotoxicosis there is a lag period before the drug exerts its action. When the administration of the drug was started two days before the expected premenstrual rise in temperature, the temperature change was eliminated and the usual concomitant symptoms were also absent. From this it appears that the premenstrual temperature change is brought about in the final stage by over-activity of the thyroid gland.

Conclusions

In the majority of women there is some modification of the temperature chart during the days immediately preceding menstruation. This change occurs in pulmonary tuberculosis in early, as well as in advanced, cases. In patients with pulmonary tuberculosis it tends to be more pronounced and of longer duration than in normal subjects. This premenstrual phase gradually diminishes in conjunction with decreasing tuberculous activity. As an indication of activity it can be regarded in the same light as a persistently raised erythrocyte sedimentation rate, and may be ignored in deciding increases of exercise. The change is probably brought about through the agency of the thyroid gland, and can be abolished by the use of thiouracil.

I wish to thank Dr. Dennison Pickering, medical superintendent, for permission to publish this paper and for his interest, advice, and criticism; also Dr. Elsie Watchorn, of the Biochemical Laboratory, Cambridge, for help in obtaining a number of the control temperature charts; and Genatosan Ltd. for a supply of thiouracil.

BLINDNESS IN AN URBAN CENTRE IN NIGERIA

BY

FRANCIS L. STOCK, M.B., B.S., F.R.C.S., D.T.M.&H.
Medical Officer, Colonial Medical Service, Nigeria

In Sept., 1944, a census of all blind persons was held in Yerwa, the chief town of Bornu Province, Northern Nigeria, in order to ascertain the percentage of blind persons in the community and so far as possible the cause of this blindness. Up to the present time it is believed that no figures have been published relating to the incidence of blindness among West African natives, and although the present series is not large it is probably representative of other urban centres in Northern Nigeria which have a similar climate and in which the same diseases are prevalent.

Yerwa is a town of approximately 35,000 persons, situated in the north-eastern corner of Nigeria and at the southern edge of the Sahara Desert. The climate is intensely dry during the greater part of the year and dust storms are very common. The average annual rainfall of 25 inches falls chiefly in three months (July to September), with slight showers between April and June and in early October. As a rule no rain falls in the remaining five months of the year.

The figures for the total number of blind persons were computed by the local Native Authority, and may be taken as fairly accurate but probably slightly below the correct figure. It was noticed during the examinations that on two occasions the ward head produced more males or females than had been declared in his ward, and also that only three children below the age of 12 years were brought for examination. It is probable that a certain number of cases of blindness in young children have been concealed, for, as will be seen from Tables II and III, 37% of all persons examined had become blind before the age of 10 years.

Owing to administrative difficulties it was not possible to examine all the blind persons in the town. Slightly more than 50%, however, were examined, including a representative number of both sexes and of all age groups except young children. The results of the census are summarized in six tables.

TABLE I.—Incidence of Blindness among the Community (Figures given by the Native Authority)

Ward	Population	Number of Blind Persons		
		Male	Female	Total
Shehurn North	—	52	42	94
Shehurn South	—	30	89	119
Zongo	—	3	7	10
Bulabulun	—	19	26	45
Hausari	—	17	17	34
Fezzan	—	11	9	20
Mafoni	—	62	101	163
Gambaru	—	6	6	12
Totals	34 425	200	297	497

The disparity of the number of blind persons among the different wards is due partly to variations in size between the wards, but chiefly to the degree of proximity between the ward and the chief market. It will be seen that the incidence of blindness among the community is approximately 1.4%, but it is certain that this is an under-estimate, and the correct figure is probably between 2 and 2.5%. In any case it is considerably

TABLE II.—Present Age of All Blind Persons Examined

Age Group	Male	Female	Total
0-5	1	0	1
6-10	21	8	29
11-20	26	24	50
21-30	38	25	63
31-40	26	18	44
41-50	24	10	34
51-60	14	9	23
61-70	6	4	10
71-80	—	—	—
All ages	156	98	254

lower than the figure (5%) given by Rosset Berdez for South African natives.

TABLE III.—Age at Onset of Blindness

Age Group	Cases	% of Total
0-5	61	24.1
6-10	34	13.3
11-20	61	24.1
21-30	27	10.6
31-40	24	9.4
41-50	14	5.5
51-60	17	6.7
61-70	13	5.2
71-80	3	1.2
All ages	254	—

In Tables II and III the ages are only approximate, for the average native has no reliable means of knowing the date of his birth. The majority, however, are able to refer the date of their birth to some contemporary historical event, and in consequence the approximations are probably not greatly in error.

TABLE IV.—Caustion of Blindness in Infancy (Age Group 0-5 Years)

Causal Disease	Cases
Conjunctivitis	29
Smallpox	31
Other causes	1

Of the group of persons who became blind before the age of 5 years (Table IV) many were not certain whether they became blind within a few weeks of birth or later, but none could ever remember seeing. If all these cases of conjunctivitis, however, are classed as ophthalmia neonatorum the proportion of cases due to this cause would be 11.4%, as compared with 6.2% in the Counties of London and Middlesex, recorded by Sorsby (1945). In view of the very septic conditions which prevail at childbirth in this part of Nigeria and the very high incidence of venereal disease, it can safely be assumed that this is not an under-estimate. With regard to the incidence of venereal disease in this area it is of interest to note that during the four years 1941 to 1944, inclusive, venereal disease accounted for between 35 and 40% of all new patients attending the Bornu Native Administration Hospital.

TABLE V.—Caustion of Blindness in All Age Groups

Causal Disease	Cases
Conjunctivitis	59
Scrofula	44
panophthalmitis	103
Smallpox	103
Penetrating wound of the globe	2
Glaucoma	10
Cataract	25
Infantile cataract	1
Cerebrospinal meningitis	3
Other causes	7
Total	254

The high proportion of cases which occur as a complication of smallpox (Table V) is in accordance with the findings during the epidemic of this disease between November, 1943, and February, 1944. During this period it was noticed that almost every severe case of smallpox developed a very severe conjunctivitis, although there were not necessarily pocks on the conjunctiva itself. With energetic treatment very few of these developed any serious after-effects. Medical facilities in Bornu are, however, in their infancy, and it is reasonable to suppose that a high proportion of these cases would have become blind in the earlier days, when treatment was not available.

Many cases of severe conjunctivitis admitted to the hospital for treatment and which respond only with difficulty to routine measures are in fact cases of keratomalacia due to a vitamin A deficiency, which is very prevalent. These cases respond rapidly when vitamin A is given.

Owing to the overwhelming number of cases in this series due to either conjunctivitis (including keratomalacia) or smallpox, it is not possible to draw any conclusions as to the relative importance of hereditary and developmental defects from the small number which remain.

TABLE VI.—Occupation or Means of Subsistence of Blind Persons

Occupation or Means of Subsistence	Male	Female
Rope-maker	37	—
Water-seller	1	—
Corn-grinder	—	3
Grass-seller	1	—
Tanner	1	—
Well-digger	1	—
Muezzin	1	—
Telephone switchboard operator	1	—
Begging	83	75
Maintained by relatives	30	20

Many of the men who stated that their occupation was rope-making (Table VI) also said that they did not earn enough money at this trade, and resorted to begging as a subsidiary means of subsistence.

Summary and Conclusions

The results of a census of blind persons in a typical urban centre in Northern Nigeria are described and classified. The series is small, but it is thought that similar results would be obtained from a census taken in other urban centres in the same area—and there are many such centres. The incidence of blindness given in this census is 1.4% of the population, but owing to concealment in young persons it is thought that the true figure may be nearer 2.5%.

It is believed that at least 80% of the cases of blindness could be prevented by widespread compulsory vaccination satisfactorily performed, education with regard to both the purpose of vaccination and a more suitable dietary vitamin A or its precursor, and by a multiplication of the existing medical facilities to ensure that all cases of conjunctivitis receive adequate treatment. The problem of venereal disease, which is almost universal in this Moslem community, is one, however, to which there is as yet no solution.

Medical Memoranda

Severe and Long-standing Headache due to Dental and Antral Infection

The following is a case of long-standing headaches showing fairly classical symptoms of migraine, which was allergic in character. The patient's trouble seems to date back to his dental sepsis, only part of which was removed by dental extractions, residual infection persisting in the spongy bone which used to house the roots of the teeth and which formed the floor of the antra. His headaches increased in frequency and severity after edentulation. The curtain of mucosa dividing the right antrum into two compartments was probably cystic and of dental origin, and was capable of becoming very oedematous, shutting off ventilation from the normal ostium. It would suggest that the bacterial allergy had some influence on the vasomotor control of the intracranial membranes and became a strong contributory factor to the headaches.

CASE HISTORY

The patient was a gardener aged 60. Intermittent headaches began 30 years ago while serving in the Army during the war of 1914-18. He was discharged from the Service as unfit on account of these headaches, with the diagnosis of migraine. While in the Army he had several dental extractions, but without any relief from the headaches. On returning to civil life these continued, and he had all his teeth removed. They were, from his account, definitely carious.

For some years after their removal he still experienced a sensation of toothache in the gums. As time went on the headaches became more frequent and more severe, until he was having two or three each week. The attacks began during the night and continued for 24 to 36 hours. The pain usually started in the cervical and occipital regions, reaching upwards and forwards to the temporal region, where it became localized. The pain was always more severe on the right side, and he described it as a severe thumping sensation: when he put his head down on to a pillow it felt as if it were being bumped up and down, and he says he felt that if only a hole could be bored through he would get relief! His case was investigated at several of the London hospitals, with the same diagnosis—migraine—and he was advised that little could be done for him.

When I examined him in February, 1945, he felt he could not go on much longer. He appeared distressed and fatigued. On a full

clinical examination nothing was found to account for his symptoms. His sinuses and alveoli were x-rayed. There was a large shadow in the right antrum suggesting a polypus, with some thickening over the floor of the left antrum. Further x-ray films were taken, this time after displacement with lipiodol; these showed a very irregular filling of the right antrum and a moderate degree of thickening of the mucosa over the floor of the left antrum. No swelling of the mucosa was noted upon the posterior wall of the antra. Other sinuses appeared normal. The alveoli of the upper jaw showed a marked osteoporosis.

It was decided to explore both antra, and he was admitted to hospital, where a large sublabial incision was made on both sides, exposing the upper part of the alveoli and the antero-lateral wall of the antra. When the right antrum was opened a pale oedematous curtain of mucosa was seen stretching from the roof to the floor of the antrum, dividing it into two compartments. This was removed and the normal opening of the antrum was explored and found to be patent. The whole of the mucosa was stripped from the antrum and a considerable amount of the cancellous bone forming the floor of the antrum was removed. A naso-antral opening was made and the wound stitched with fine silk.

The mucosa in the left antrum was thickened, with a moderate degree of polypoid degeneration. The mucosa and the polypi along the floor were removed together with the bone forming the floor and part of the alveolus. A naso-antral opening was made and the wound stitched with fine silk.

The patient made an uninterrupted recovery and was discharged from hospital within ten days. Since he was operated upon he has been entirely free from headaches, and remarks that his head now feels much lighter.

R. S. GLENNIE, M.R.C.S., L.R.C.P.,
Senior Assistant Surgeon,
Metropolitan Ear, Nose, and Throat Hospital.

Bilateral Cryptorchidism in Three Brothers

I have had little opportunity of going deeply into the literature of cryptorchidism, but, so far as I can gather, there has been no recorded case of its occurrence in three brothers. The following instance may therefore prove of interest.

CASE HISTORIES

In 1944 a father brought his son, then aged 10, to see me, saying that he appeared to have something wrong with his scrotum. I examined the boy, and found no evidence of testicles in the scrotum or inguinal canals. He had never felt any pain in either inguinal region. No other abnormality was discovered, and he was otherwise healthy. He was treated with pregnyl without result. Some months later his mother brought a younger brother, aged 7, to me, as she thought he needed circumcision. While examining him I noticed that his scrotum was empty and there was no trace of testicles in the inguinal canals. No other abnormality was found, and he was quite healthy. He was subsequently circumcised, but his cryptorchidism still remains. I knew there was a third brother, aged 5, and I rather jestingly said to the mother that perhaps it would be as well if I had a look at him also. She brought him to me next day, and in his case too there was no evidence of testicles in the scrotum or inguinal canals. There was no other abnormality, and he was quite healthy. The mother and father of the boys are normal and healthy, and I cannot find that there has ever been cryptorchidism in either of their family histories. They have no other children.

At the end of January, 1945, the eldest boy was admitted to Harefield County Hospital under the care of Dr. Reginald Lightwood, where he remained until March 10. While there he was treated with injections of antuitrin S rising from 1 ml. to 3 ml., given twice weekly—a course of 12 injections in all. At the time of his discharge there was no evidence of the descent of either testicle. I very recently examined the three boys again, without finding evidence of testicles in scrotum or inguinal canals of any of them.

So far as my own experience goes, bilateral cryptorchidism is very uncommon, although I have seen a few cases of the unilateral variety. Thorek (1924) puts the incidence at 1 in 500, stating that the condition is usually unilateral. Gallagher and Brouha (1944) found the condition in 0.5% of high-school boys. Thompson and Hechel (1941) had 25 bilateral cases in a series of 62. Williams (1936a, 1936b) found 1.8% of unilateral and 1% of bilateral cases in a series of 2,104 boys. In view of the correspondence recently appearing in the *B.M.J.* under the heading "Descent of the Testis," the condition of these three brothers would seem to be of especial interest and to bear out the contention of Mr. A. W. Badenoch (1945) that "the descent, therefore, of the testis is almost entirely due to hormonal influence." I am indebted to Dr. Reginald Lightwood for having treated the eldest boy at Harefield, and to Mr. George Bonney, who furnished me with the references quoted.

Reviews

PHYSICAL DIAGNOSIS

Physical Diagnosis. By Ralph H. Major, M.D., Professor of Medicine in the University of Kansas. Third edition. (Pp. 4-4, 457 illustrations. 25s.) London: W. B. Saunders Company, 1945.

This is probably the most attractive textbook of physical diagnosis on sale at the present time. It is not too large, is beautifully produced and is illustrated with a magnificent collection of photographs. Some of these delight us by the skill with which a typical picture has been caught, as in the photograph of Buerger's disease. Others are impressive by the clever photographic technique, as for example, the whole series of pictures of the lips, tongue and teeth. Pictures make such a lasting impression on the beginner that it is perhaps a pity that haemochromatosis is depicted in a woman when it is so much commoner in men. Another commendable feature is the reproduction of illustrations from the original accounts of disease and the numerous historical notes. If we might venture a criticism, it would be to doubt whether this and similar books adequately represent the practice of to-day. Physical diagnosis developed in the age of therapeutic nihilism, when physicians spent their time in the wards eliciting physical signs and explaining them by rather dubious principles of physics, and when these wards contained numerous cases of valvular disease of the heart, aneurysm, and advanced tuberculosis. Unless he is interested in the art purely for art's sake, we cannot imagine a modern physician looking for Litten's sign of diaphragmatic paralysis. It seems also a little unbalanced to devote so many pages to the heart and lungs, and so few to structures like the joints, the sciatic nerve, and the peripheral circulation. The student of to-day will see much more hypertension and arteriosclerosis than endocarditis and he will, we hope, learn to diagnose pulmonary tuberculosis at an earlier stage than that of Hippocratic succussion and the *bruit d'airan*. There is, in fact, a place for a textbook of physical diagnosis more suited to this neotechnic, geriatric age. But let us make no mistake about it: it would have to be very well done indeed to be as attractive a book to the student as Prof. Major's.

TUBERCULOSIS—AS A WHOLE

Tuberculosis—As a Whole. By E. Ashworth I. R. Carris, M.D. Third edition. (Pp. 154, plus 7d. postage.)

Whenever the clinician meets with a case of pulmonary tuberculosis, or even some other chest disease, he is unpleasantly reminded that the condition in the unfortunate patient has a background. Tuberculosis is a disease of chronic causes, its origin has often to be guessed, and its social environment is extremely important. Many books on "chest diseases" give confident descriptions of pathology, physical signs, and treatment. But few are capable of sketching this wide hinterland which often dwarfs the mere clinical problem. Dr. Ashworth Underwood's manual may be warmly recommended. Its description of the scientific basis of the disease is full enough for the medical student, the nurse, or the social worker, and the latter sections dealing with management are even more useful. We are taken rapidly through collapse therapy, orthopaedic manifestations, and laboratory methods, and there is a satisfactory account of the routine of the tuberculosis dispensary with all its social implications. Rehabilitation is given adequate pages, and there is a useful glossary and list of recommendations for further study.

It is much more difficult to conceive and carry out a small book like this than a large tome. Every writer knows that compression plus lucidity is a result most difficult to achieve. The author has succeeded, and this book can be welcomed both for its own virtues and as a sign of the times. The teaching to undergraduates of the whole theory and practice of tuberculosis control is much behind the necessities of to-day. The old fashioned point of view which began with the physical signs and ended with a pneumothorax refill has to be replaced by a much larger conception. While Dr. Underwood does not claim that environment is more important than the individual

patient's disease, he does make clearly evident the relation between the two. If only for its lesson that the tuberculosis physician must take total views this book is to be welcomed.

A POST-WAR TEXTBOOK OF PUBLIC HEALTH

Textbook of Public Health (formerly Hope and Sallibass). By W. M. Frazer, M.D., D.P.H., and C. O. Stallibrass, M.D., D.P.H. Eleventh edition, revised and enlarged. (Pp. 571, illustrated. 25s., plus 7d. postage.) Edinburgh: E and S Livingstone, 1946.

It is six years since the tenth edition of the standard textbook on public health, by Frazer and Stallibrass, has been issued, and it is now out of print. A new edition is therefore valuable for the new student. The eleventh edition has been revised and brought up to date in two ways. Much of the ephemeral war-time stuff has been omitted and a good deal of material has been added notably a chapter on the social services.

A book published immediately after the war cannot escape certain defects. It has difficulty in striking a just balance between the old and the new, and in assessing the relative importance of tendencies in legislation and in practice. The immense changes in political structure since the end of the war and the effects of a national health service on public health administration cannot yet be fully estimated, and perhaps it is only right that this textbook should deal with the things that are established. Speculation would have been out of place in a work of this kind. Nevertheless one feels a sense of disappointment, almost amounting to frustration, in the lack of reference to such measures as the Education Act, 1944, and the legislation on behalf of disabled persons. It will take time before the new trends in thought and action can be really incorporated in a standard work. Meanwhile we should welcome a useful and comprehensive textbook which may well mark the dividing line between the duties of the medical officer of health under forthcoming legislation and those assigned to the medical officers of the new regional authorities for medical care.

A SURVEY OF NUTRITION

Dietary Therapy. Clinical Application of Modern Nutrition. Edited by Michael G. Wohl, M.D. With foreword by Russell M. Wilder, M.D., Ph.D. (Pp. 1029, 93 illustrations. 40s.) London: W. B. Saunders Company, 1945.

This book is a symposium on nutrition by 58 different contributors, all of whom are authorities in their respective fields. It is not, as its title might suggest, a treatise on dietetics but an up-to-date and wide survey of nutrition from the biochemical, dietetic and clinical aspects. The titles of the chapters range from oxidative enzymes to the nutrition of factory workers. It is clear that with such a wide range of interest each chapter needs to be written by an expert.

The book is divided into three parts. In Part I, which deals with normal nutrition the role of various nutrients, including vitamins and trace elements, is discussed. Part II is devoted to nutrition in infants and the aged, in pregnancy, and in relation to infection. Part III deals with the dietetic treatment of disease. Deficiency diseases are included in the chapters on vitamins, which occupy about a sixth of the book. There are also chapters on amino-acid therapy, nutrition in industry, nutrition and income, and the care of the surgical patient. Useful features of the book are summaries and bibliographies at the end of the chapters and a comprehensive index of 43 pages.

Though the advice given on the dietetic treatment of disease is perfectly sound it cannot be followed at present on this side of the Atlantic, not even in the blackest of black markets, as many of the foods are not obtainable, either at all or in the quantities mentioned. However, this is not a reflection on the book but on the food situation in this country and Europe. Part III of *Dietotherapy* will be even more useful when we have a greater quantity and variety of food.

The literature on nutrition is scattered throughout many publications in several unrelated fields of knowledge, and the general reader has the greatest difficulty in keeping abreast of it. The critical and authoritative reviews in this book contain up-to-date information on those aspects of nutrition likely to be of interest to the general medical reader, particularly on the prevention and treatment of disease. The editor and the many contributors are to be commended on the production of one of the best collections of reviews on the clinical applications of nutrition so far published in book form. *Dietotherapy* should be in the hands of all who are interested in nutrition.

SPINAL INJURIES

Traumatismes de la Moelle et des Racines. Sciatique Traumatique. By R. Thurel. (Pp. 76; illustrated. 75 francs.) Paris: Masson et Cie. 1944.

Injuries to the spine may occur in peacetime as well as in war, and this complete review of their diagnosis and treatment in a brief monograph is certainly useful. Such injuries are dealt with in respect of immediate results and late effects. All such wounds require early surgical attention, and, if the cord is only partially destroyed or the lesion affects the cauda equina, care should be exercised to relieve all pressure. Late results call for laminectomy and removal of foreign bodies, but also for care in readjusting vertebral dislocations or displacements. The chief interest of the book will be found in the excellent discussion of root sciatica. The author considers that, if the root pain is chronic or recurrent, surgery is always called for. Having excluded bone, joint, or arterial disease, he uses diagnostic novocain injections, and then, since laminectomy is in his opinion indicated, he always injects lipiodol, preferably by the suboccipital route. Most cases are found to be due to displaced disks or herniated nuclei, but some are due to hypertrophy of the yellow ligament, or to adhesions following arachnoiditis, which can be divided. In severe cases the posterior root of L 5 or S 1 may be cut. The sections on diagnosis and surgical technique are admirably clear and the whole discussion will amply repay study.

Notes on Books

Bulletin No. 8 of the Department of Labour and National Service, Australia (39 pp) deals with *Factory Planning: Part I. Some Aspects affecting Working Conditions*. It contains the pooled experience and ideas of a considerable number of Australian manufacturers, engineers, and architects, and relates more especially to industrial buildings designed and erected during the war years. The first section describes natural lighting, artificial lighting, and colour of walls, chimneys, etc. The second section relates to natural and mechanical ventilation, and to heating and air-conditioning. The effect of climate, which differs so widely in various parts of Australia, is also discussed. The third section of the Bulletin considers the layout, construction, and equipment of factories, and, like the rest of the Bulletin, it is most excellently illustrated. Copies may be had from the Department of Labour and National Service, 37, Swanston Street, Melbourne.

The third edition of Dr. D. A. RHINEHART'S *Manual of Roentgenographic Technique* (Henry Kimpton; 28s.) is unchanged in its general plan, but includes some new material and illustrations. It is a pity that the author did not take the opportunity to use modern apparatus in the illustrations indicating technique. The universal Coolidge tube in a lead-glass bowl was in vogue twenty-five years ago. The book, which contains a good but elementary account of x-ray technique generally, may be found of use by student radiographers: it is not sufficiently full to be of much interest to radiologists and is too technical for clinicians, but the fact that it has reached a third edition proves that it supplied a need.

Histoire de la Science, a volume of 820 pages, is the work of a French scientist, PIERRE ROUSSEAU, who has set himself the task of collating the world history of science down the ages. Science, the daughter of sorcery, was born about the year 4000 B.C. in the region of South Mesopotamia on the Persian Gulf. Many thousands of tablets recording Sumerian observations were made of soft clay, which was then baked. Using at first simple numerals, the Egyptians and Babylonians later evolved algebra. The next step was in Ancient Greece, where mathematics and geometry appeared. M. Rousseau takes us from the time of Archimedes to the scientific revolution of the 19th century and the contemporary activities of Crookes, the Curies, and Rutherford. Einstein's relativity and also atomic energies are reviewed and explained. The author concludes his work with an appeal for the continuance of pure science and disinterested research. He decries scientists who limit their work to utilitarian ends, and in doing so recalls the early experiments of Volta and Ampère, which, though limited at the time, contained the germs of modern electrical technique. This book is an elaborate and useful work for those who are interested in science in all its aspects. It is published at 148 francs by Librairie Arthème Fayard, 18, Rue du Saint-Gothard, Paris.

The American Group Therapy Association announces the publication of a *Bibliography in Group Therapy*. The work consists of four sections: (1) bibliography in group therapy, (2) group psychotherapy in the armed services, (3) symposia, (4) books. The bibliography can be obtained by writing to the Association at 228, East 19th Street, New York 3, N.Y. The price of it is stated to be 40 cents.

Preparations and Appliances

FACIAL SPLINT FOR TREATMENT OF BELL'S Palsy

Dr. J. P. PRACY writes from Barnet:

Treatment of patients with seventh-nerve paralysis by the strapping system described by Pickerill and Pickerill¹ has revealed certain disadvantages in the method. The strapping rapidly becomes dirty in the atmosphere of modern cities. It is rather unsightly and has a tendency to work loose, and male patients wearing it find shaving difficult if not impossible. The method has worked well apart from these disadvantages, and to overcome them while still employing the principle of traction on sound rather than paralysed muscles a splint has been evolved.

DESCRIPTION

The instrument is an elongated racket-shaped loop of copper wire (14 S.W.G.). It is covered with thin rubber tubing. The "handle" of the racket (A) is 5 in. (12.5 cm.) long and the loop (C) about 6 in. (15 cm.) long and 1½ in. (3 cm.) wide. The apparatus is easily made from a single length of copper wire about 18 in. (46 cm.) long. The joint at B is soldered, but in the first two models made it was simply twisted and apparently worked satisfactorily.

METHOD OF APPLICATION

This will be clearly seen in the drawing. The splint is bent to fit the individual patient's face as follows. The elongated sides of the loop are first bent in the centre, and applied to the upper and lower jaws. The handle is then applied to the affected side of the face, and the end hooked round the pinna of the ear. The end of the loop on the good side of the face is secured with a small piece of strapping, and the unaffected side is drawn over to the affected side before the strapping is stuck.

It has been found that by using eyelet holes and a collar stud in the strapping the splint may be readily removed for the purposes of washing, shaving, and the application of electrical stimulation. However, the splint should otherwise be worn at all times and only removed for the specific purposes mentioned above.

The strapping is prepared as follows. A 4½-in. (11.5-cm.) length of 1½-in. (1.25-cm.) strapping (AB) is cut off—see (1) on diagram—1½ in. (4 cm.) at one end (BC) is folded back on itself, stuck, and two small eyelet holes cut in it, leaving 1½ in. of adhesive to stick to the face—see (2). The end C is then taken through the loop of the splint—see (3)—and the stud passed through each of the eyelet holes in turn.

To remove the splint the stud has merely to be taken out, and the strapping remains in exactly the correct position when the splint is replaced. It is easy to take up any slack in the splint by bending rather more of the handle round the pinna on the affected side.

I would emphasize that the good side should be pushed over to the affected side when securing the small piece of strapping initially. Furthermore, considerable traction can be obtained by this method, and care should therefore be taken that too much is not applied

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY APRIL 6 1946

NORTHERN IRELAND'S ANTITUBERCULOSIS
LEGISLATION

Northern Ireland, which in recent years has considerably enlarged its institutional provision for tuberculosis, is setting about the combating of this scourge by preventive and protective measures. A Government Bill has been introduced into the Northern Ireland House of Commons which is modestly described—modestly in view of its far-reaching character—as a Bill to make better provision for the prevention and treatment of tuberculosis. It goes much further than the tuberculosis schemes which have been operative in Great Britain since the Astor departmental committee of thirty or more years ago. In the first place a tuberculosis authority, a body corporate, is to be set up for the whole country. This body will have the duty of making provision for the accommodation and treatment of tuberculous persons, for the detection of cases, and for the prevention of the disease by educational and other methods, including courses of instruction for medical students, doctors, and nurses. The authority will be able to purchase or lease land and acquire or construct buildings to be used as hospitals, sanatoria, dispensaries, clinics, health centres, occupational colonies—as may be necessary. It will maintain and educate tuberculous children or children who have recovered from tuberculosis, or children who have been in contact with infectious cases in their homes. Another of its duties will be to train people in methods of detecting, preventing, and treating tuberculosis, and to that end testing apparatus and equipment and maintaining laboratories for research. Again, the authority may contribute to the support of any association for training nurses or to any benevolent association in line with its purpose. The authority to which such wide powers are to be given will consist, as to the majority of its members, of nominees of the local authorities—four from the Belfast and one from the Londonderry county borough councils, two from each of the county councils of Antrim and Down, and one from each of the four other county councils. In addition there will be four other members nominated by the Minister of Health and Local Government, and it will be possible to co-opt one or two further members. The members are not to be paid any salary or fees, but only reimbursed their expenses. There are provisions in the Bill for the transfer of people engaged at present in tuberculosis work in the local authorities.

Whenever a medical practitioner intimates to the authority that a person exhibits symptoms indicating any significant tuberculous condition that person may be called upon to be examined medically for the purpose of diagnosis. If a practitioner becomes aware that a patient

whom he is attending is suffering from tuberculosis he must send a certificate to the authority (for which there is to be a prescribed fee) within 48 hours; similarly, if he signs a death certificate in the case of a death from tuberculosis, and if the deceased had not previously been certified, he must again notify the authority. Failure to make these notifications will mean a fine up to £5 for the first offence and up to £25 for a second or subsequent one.

The authority will have power to require any person living in habitual contact with a person suffering from tuberculosis to be examined by a medical officer. It can also apply to a court of summary jurisdiction for an order to detain any person suffering from tuberculosis of the respiratory tract should he be in an infectious state and should his home circumstances be such that proper precautions are not or cannot be taken. If the court is satisfied it may order the person to be kept in a hospital or institution for not more than three months, and the period may be renewed if the same conditions still obtain. The medical examination which the court may require before proceeding to exercise its powers of detention may be by any medical practitioner, not necessarily the nominee or employee of the authority. The authority is responsible for the cost of the removal and maintenance of the person and, if necessary, for the maintenance of his dependants. If during the period of detention his condition improves, so that there is no longer serious risk of infection, or if his home circumstances become such as to permit the necessary precautions to be taken, he may be at once released from institutional control.

The Act is to be called the Public Health (Tuberculosis) Act (Northern Ireland), 1946. It will repeal the Tuberculosis Prevention Act, 1913, and most of the earlier Act of 1908, as well as parts of the National Health Insurance Acts. In the title of the Bill "other chest conditions and other orthopaedic conditions" are mentioned, but there is no reference to them in the clauses; all the provision is against tuberculosis. It will certainly be an interesting experiment to watch as applied to a community of something over one and a quarter million people who were once described by a British Prime Minister as "without exception the toughest, most dominant, most irresistible race that exists in the universe at this moment."

FOLIC ACID FOR BLOOD DISORDERS

For over two years folic acid has been the subject of investigations which looked as if at any moment they might result in a major therapeutic advance. In October, 1943, Daft and Sebrell¹ described the successful treatment of granulocytopenia and leucopenia in rats with crystalline folic acid. They produced agranulocytosis by feeding the rats on a diet containing 1% sulphaguanidine or sulphasuxidine. This constituent reduced bacterial activity in the intestine and therefore reduced the formation of substances essential for nutrition. As a result, after a variable length of time (30–122 days) there was a reduction in the leucocyte and particularly in the granulocyte count. It may be noted that the diet contained thiamin (B₁), pyridoxine, riboflavin,

¹ *Publ. Hlth. Rep. Wash.*, 1943, 58, 1542.

calcium pantothenate, nicotinic acid, choline chloride, and biotin. When the leucopenia was established, four days' administration of folic acid raised the white count from a mean figure of 2,700 to 14,400 per c.mm., and the percentage of granulocytes from 1 to 39. This was the first discovery. It was a result of observations that leucopenia was cured in the rat by concentrated extracts from liver, the preparation of which suggested that the substance stimulating leucocyte production might be the growth factor for *Lactobacillus casei*²; this was later named folic acid.³ When folic acid was crystallized,⁴ therefore, it became possible to test and establish the suggestion.

There has been, however, another direction in which folic acid has become a substance of great interest. Its crystallization led to its identification with vitamin B₁₂—an anti-anaemia factor for the chick.⁴ The outcome of the indication that folic acid was concerned not only with the production of the white cell in the bone-marrow but also with the production of the red cell is that Spies⁵ has recently described the successful treatment of macrocytic anaemia with folic acid. Spies has been working in the southern part of the United States at a centre he established in Alabama, where severe malnutrition is still relatively common. As far back as 1930 he observed that many with pellagra suffered from a macrocytic anaemia exactly like a pernicious anaemia, except that there was no achlorhydria. This nutritional macrocytic anaemia was not due to lack of Castle's intrinsic factor, for the gastric juice of these patients, when incubated with meat, caused a reticulocytosis in patients with pernicious anaemia. Spies therefore began, at Birmingham in Alabama, to hunt for the missing nutritional factor. His centre derived financial support "particularly through large grants from the Research Corporation of New York and the Eli Lilly Company of Indianapolis." After the identification of folic acid with the anti-anaemia factor in the chick, Spies must obviously have had a keen interest in supplies of folic acid. But its extraction from liver, yeast, and other sources results in a poor yield, and only its synthesis could make possible sufficient supplies for testing. Spies's paper begins: "In August, 1945, the synthesis of folic acid (*L. casei* factor) was announced by sixteen investigators (Angier *et al.*).⁶ The following month Spies, Vilter, Koch, and Caldwell⁷ reported the results of the first clinical use of synthetic folic acid in the treatment of macrocytic anaemia." Was ever such perfectly timed co-operation between the chemists of the manufacturing firm and the clinical team? This represents a very high degree of research organization. The results are that out of 42 cases of macrocytic anaemia 26 responded to administration of folic acid, and of these five were patients with Addisonian pernicious anaemia. This effect of folic acid in pernicious anaemia is of the greatest interest, and suggests that the position of Castle's intrinsic and extrinsic factors will require reconsideration. Among the other patients successfully treated were 8 with sprue, in whom not only did the anaemia disappear but the liquid fatty stools turned to solid brown faeces.

Since the investigation is going on in the United States, we may expect that future developments will not be long delayed. The pace there is very hot. In the meantime we may ask, "What supplies of folic acid are likely to be available in this country?" They may not be urgently required for treating pernicious anaemia or for nutritional macrocytic anaemia, since we have remedies for the former and the latter does not occur in a population which eats meat. Sprue is, however, not uncommon among returned soldiers, and undoubtedly if folic acid is a remedy for agranulocytosis that alone provides a demand for it. Actually the relation of folic acid to agranulocytosis is not so clear to-day as it seemed in 1943, for Daft, Kornberg, Ashburn, and Sebrell⁸ have described anaemia and agranulocytopenia in rats deprived of pantothenic acid. While they say that "the granulocytopenia, when unaccompanied by anaemia, probably was a sign simply of an *L. casei* factor (folic acid) deficiency," some doubt remains in the reader's mind whether a fall in granulocyte count will always be due to lack of folic acid alone.

It is to be hoped that British manufacturers are paying full attention to the production of folic acid, despite this uncertainty. Their task is not made easier by the strange fact that those announcing the synthesis in the pages of a scientific journal do not describe how they have achieved it.

PROLONGING PENICILLIN ACTION

In a patient with functionless kidneys a few hundred units of penicillin would suffice to produce an ample therapeutic concentration in the blood. That it is necessary to give doses enormously greater than this is due to the fact that the normal kidney excretes it far too rapidly for therapeutic convenience or economy; the average time spent by each molecule of penicillin in the circulation has not been calculated, but it is probably less than fifteen minutes. There are three reasons for trying to prolong the effect of each dose, and three principal methods of doing it. The reasons are economy, which is a rather less pressing motive than it once was; convenience, particularly in treating the ambulant patient with gonorrhoea or syphilis; and the patient's comfort, particularly if he is severely ill and in need of prolonged sleep. One method of securing a prolonged effect which is far from serving the needs of economy is to give an enormous dose, as practised by Lourie and others⁹ in the treatment of syphilis. A second is to obstruct renal excretion. Nephritis or other severe renal damage has this effect, and abnormally high concentrations of penicillin have been observed in the blood of such patients receiving ordinary doses. Delayed excretion can be secured by the simultaneous administration of diodrast or paraaminohippuric acid. Although the use of the latter has been studied extensively, it does not appear to have achieved therapeutic popularity. The third possible method is to secure slow absorption from the site of injection. A special example of this is to inject the whole of the daily dose into a large abscess cavity, thus producing both a local and a systemic effect. M. E. Florey and N. G. Heatley¹⁰ found that after injection of 120,000 units into an empyema a bacteriostatic concentration persisted in the blood for 24 hours. When injections are given in the usual way, some degree of prolongation of effect has been claimed for subcutaneous as compared with intra-

⁹ *Lancet*, 1945, 2, 696.

¹⁰ *Ibid.*, 1945, 1, 748.

muscular injection¹¹ the addition of vasoconstrictors to the solution,¹ using 5% glucose instead of saline as the vehicle¹¹ and applying an ice bag to the site of injection.¹⁴

More popular and promising than any of these proceedings is the incorporation of penicillin in solid form in a beeswax-peanut oil mixture, as first advocated by Romansky and Rittman.¹⁵ From a considerable number of subsequent papers it has not been altogether clear how effective this proceeding is, but the latest information appears conclusive. When calcium penicillin of a high degree of purity is employed 300,000 units can be suspended in only 1 ml of peanut oil containing 48% of beeswax; this greater concentration apparently makes for slower absorption. A single 1 ml dose of this material injected intramuscularly was found by W. M. M. Kirby *et al.*¹⁶ to produce an assailable blood level for from 8 to 24 hours, but the results were somewhat erratic, and slower and more regular absorption followed subcutaneous injection. 14 out of 25 patients so treated had an assailable blood level continuously for 20 hours or more. There is a minor practical disadvantage: this material is exceedingly viscous and even after warming can be forced through a needle only with difficulty. For the simplified treatment of venereal disease this is evidently the best method yet evolved, but it calls for a relatively large dose—even 600,000 units per injection has been used in the USA in order to produce a full 24-hour effect—of highly purified penicillin. It would be interesting to know how soon the supply position in this country will justify extravagance for the sake of convenience.

TOXICITY OF THIOURACIL

The Americans show great enterprise in organizing the collection of evidence on particular points. The latest example of this concerns the toxicity of thiouracil, and the evidence has been compiled by F. D. Moore.¹⁷ He has succeeded in getting details of toxic symptoms from ten distinguished medical centres in America and also from University College Hospital in London. The total number of patients treated with thiouracil in these centres has been 1,091, among whom there were 19 cases of agranulocytosis, 5 being fatal. These were in high probability deaths due to thiouracil. The term "agranulocytosis" was used to mean a conjunction of depressed granulocyte count with infection, usually around the neck, throat, and floor of the mouth. The majority of these cases occurred between the fourth and eighth weeks of treatment. While the death rate from agranulocytosis in the whole series was thus 0.5%, there was leucopenia without concomitant infection in 3%, counting as leucopenia a fall in the white cell count to less than 3,000 per cmm. Himsforth says that experience at University College Hospital shows there is indeed some fall in the leucocyte count in nearly every patient if care is taken to determine the count before treatment begins. Treatment with thiouracil was continued in some of the patients with leucopenia, but in the majority it was stopped, the white count then recovered. In 5% of patients there was drug fever, and in 5% enlargement of lymph nodes or of the parotid glands.

Information on this subject is not confined to the compilation just described, for, oddly enough, in the same journal

van Winkle and his colleagues¹⁸ have been working in the same direction. They offer a survey of 5,745 cases treated by 328 clinicians. While it can be said that this investigation has not been confined to such established centres as the first, the conclusions are similar and more detailed information is given. Thus there were 21 deaths from agranulocytosis due to thiouracil, indicating a death rate of 0.4%. These investigators were able to examine the incidence of granulocytopenia in relation to the dose of thiouracil, and found that the percentage of patients showing granulocytopenia was independent of the dose. When 0.1–0.4 g per day was given 28% developed granulocytopenia, when 1.0 g or more was given 2% developed granulocytopenia. A good many patients showed leucopenia without a fall in the granulocyte count; others showed the reverse. This might suggest that leucopenia and granulocytopenia are unrelated, but actually the incidence of both in one patient was 65 times as great as it should have been if the conjunction was due to chance. Drug fever occurred in 2.7% of patients and skin reactions in 3.3%. Urticaria was the commonest. A poll was taken on the question, 'Is the incidence of toxic reactions to thiouracil greater or less than complications of present methods of treating hyperthyroidism?' The result is interesting: 78.6% said "less," and only 4.2% said "greater," the others had no opinion. Evidently four out of five American doctors think thiouracil is a good remedy. The authors state that granulocytopenia should be treated by massive doses of penicillin (500,000 units per day).

Another aspect of this second report deserves mention. The survey was the result of co-operation between six drug manufacturers and the Food and Drug Administration, and the report was sent to the Council on Pharmacy and Chemistry of the American Medical Association. The secretary of the council, in a note, urges manufacturers to show a similar spirit in other therapeutic problems of common interest.

INDUCTION OF OVULATION IN WOMEN

It was clearly demonstrated about twenty years ago that extracts and implants of the anterior pituitary could bring about follicle ripening, ovulation, and corpus luteum formation in the smaller laboratory animals. It seemed then that the application of these discoveries to the human being would be comparatively simple and needed only a gonadotrophic preparation of high potency. This early optimism faded as it was realized that the pituitary-gonad relationship is both complicated and delicately balanced. Even now it is difficult, and often impossible, to induce the human ovary to ovulate. The earlier efforts to do so were made with chorionic gonadotrophin, and were unsuccessful. It is now fairly well established that the effect of this substance by itself on the human and monkey ovary is to depress follicular activity. For anovular menstruation some workers have tried "oestrogen shock" therapy, giving a large dose about the twelfth to the fourteenth day of a 28-day cycle, in the hope of precipitating ovulation—a treatment not without some theoretical basis. When a potent preparation of a follicle stimulating gonadotrophin (from pregnant mare's serum) became available, the hopes of the clinicians were raised again. However, it seems doubtful whether ovulation can be produced by this hormone acting alone, unless it is administered intravenously. Hoffman¹⁹ concludes that ovulation in the lower animals, in primates, and in human beings depends on (a) follicle-stimulating hormone applied in correct amounts for an

adequate time to promote full ripening of the follicle; (b) the addition of luteinizing gonadotrophin at the moment when the follicle is ripe, the liberation of the ovum being dependent on a synergic action between the two gonadotrophins present in a proper proportion; and (c) the presence in the ovary of follicular systems capable of responding to these stimuli. This latter is important in practice. In many cases of ovarian underactivity associated with amenorrhoea the supply of pituitary hormones is not deficient; it is the ovaries which are refractory, and in such cases gonadotrophic hormone therapy can hardly be expected to be effective.

Most workers now use a combination of gonadotrophic principles when trying to induce ovulation in women. Some employ a mixture of chorionic gonadotrophin and a pituitary extract containing what is described as "synergic factor" (although this may be only follicle-stimulating hormone which acts synergically). Others prefer to copy what appears to be the natural cycle, injecting follicle-stimulating hormone during the first phase of treatment and chorionic gonadotrophin during the second. Among the advocates of this latter technique is Prof. E. C. Hamblen, who began this type of treatment in 1939, and together with C. D. Davis has now reviewed²⁰ the results obtained during a five-years trial of what he calls the "one-two cyclic gonadotrophic therapy." After full preliminary investigations, including hormone assays and endometrial biopsy, 116 patients with "hypofunctioning ovaries" were given ten daily injections of 400 i.u. serum gonadotrophin followed by ten daily injections of 500 i.u. chorionic gonadotrophin. To minimize the possibility of the development of an antagonistic factor or "antihormone" an interval of at least one month was allowed between two courses of treatment. The effect was judged by clinical response and by biopsy. Of 7 cases of delayed puberty, only 1 showed evidence of having ovulated after treatment, but 5 responded by uterine haemorrhage; none continued to menstruate when treatment was withheld. The menstrual irregularity continued in 14 patients suffering from infrequent and scanty periods, but 4 of them ovulated during the course of treatment. A positive response was obtained in 15 out of 31 women who had prolonged and excessive anovular haemorrhage. Half of the 14 patients who had regular but anovular menses associated with sterility ovulated, and 4 of them became pregnant, during treatment. The last group of 50 patients were apparently ovulating but showed evidence of defective progesterone stimulation of the endometrium; 9 of them became pregnant during treatment. Hamblen and Davis conclude that patients who suffer from "hypoestrinism" show a poor response, but patients having anovular ovarian cycles without "hypoestrinism" respond well; 44.8% of these showed evidence of corpus luteum formation after treatment. When pregnancy occurred the time of conception seemed to indicate that ovulation took place within 24 to 48 hours of starting injections of chorionic gonadotrophin. These results are encouraging. Nevertheless, failure to ovulate is not necessarily a permanent state, and spontaneous cure is always possible. A secretory reaction in the endometrium, or the occurrence of pregnancy, may not be related to the treatment. Finding signs of ovulation at laparotomy shortly after the administration of gonadotrophin does not permit a definite conclusion that one is the effect of the other. Hamblen's work will have to be repeated on a larger scale and by many independent workers before it can be claimed that a reliable method for inducing ovulation has been found. A good deal of evidence will be required to offset the sobering reports of, for example, Geist, Gaines, and Salmon,²¹ who

carefully investigated 91 cases in which the ovaries were available for study after treatment with hypophysial, equine, and chorionic gonadotrophins, in various combinations; in every case they failed to find evidence of ovulation which could be unquestionably attributed to the treatment.

THE BLACK HOLE OF CALCUTTA

In June, 1756, the army of Siraj-ud-daula besieged the city of Calcutta. A small band of the defenders, including civilians, with women and children, remained in Fort William, where on June 20 they were overpowered and made prisoner. That night they were shut in a small guardhouse from 8 p.m. When the guardhouse was opened at 6 o'clock next morning only a few survivors emerged. About 146 persons were incarcerated in the "Black Hole," and of these 123 perished. One contemporary writer refers to the victims as being "suffocated"; another says they were "miserably smother'd by the Heat occasioned by so many being shut up in so small a Place as to be oblig'd to Stand upon one another"; while yet another writes of the prisoners as dying "overheated and for want of water." Forty or fifty years ago standard works on hygiene ascribed the deaths to the "very impure air," but the view of Sir Leonard Hill that the cause of death was heat-stroke is now generally accepted. Macdonald Critchley has recently delved into the available records, and has made a close study of climatological and architectural data, as well as of the symptoms of the sufferers given in the original accounts. His observations form a most interesting paper.¹ The Black Hole was 18 ft. by 14 ft. 10 in. (5.5 by 4.5 m.) in plan and 18 ft. (5.5 m.) high, so that the floor space was about 2 sq. ft. (1,858 sq. cm.) and the air space 33 cub. ft. (0.9 cub. m.) per person. The walls were thick, and there were only two windows, each about 15 in. (38 cm.) square. The windows opened on to a piazza 12 ft. (3.65 m.) wide, so they were much sheltered from any breeze there might have been. The "incident" occurred on the night before the monsoon broke, and from the records of recent years it can be assumed that the maximum day temperature was about 90° F. and the minimum night temperature about 79° F.; the relative humidity would approach 90%.

Dehydration and heat exhaustion are each dismissed as unlikely to have been the cause of death. Discussing asphyxia as a possible cause, Critchley recalls the disaster of the Bethnal Green tube shelter in 1943, when 171 persons lost their lives. The coroner's verdict was "asphyxia due to suffocation by compression," and in the original records of the Black Hole there is much evidence of compression of the bodies of many of the victims, and especially of the thorax. With only 2 sq. ft. (1,858 sq. cm.) of floor space per person any agitation, panic, or struggle to reach windows must have been highly dangerous. The weaker victims, as the records show, collapsed and were trampled on, as they were in the fire at Coconut Grove, Boston, in 1942. But asphyxia due to compression does not explain the physical and mental agitation and delirium which were striking features in the Black Hole episode. It may be that there was also asphyxia due to deprivation of oxygen or poisoning with CO₂, and consideration of a survivor's narrative suggests that of these anoxia is the more likely.

Mr. C. N. Davies, who contributes a physical analysis of the conditions within the Black Hole, supports the view that heat-stroke, from heat generated by the victims themselves, was the most likely cause of death. Excess of carbon dioxide may have been a contributory factor, but the calculations suggest that oxygen lack was not severe.

REHABILITATION OF FORCES NEUROSIS PATIENTS TO CIVILIAN LIFE

BY

MAXWELL JONES, M.B., M.R.C.P.Ed., D.P.M.

Psychiatrist in Charge, Neurosis Unit, Southern Hospital, Dartford

In May, 1945, a unit was formed at Mill Hill Emergency Hospital* and sent to the Southern Hospital, Dartford, to prepare for the admission of neurotic ex-P.O.W.s requiring hospital treatment. In the four months June to October, 1945, we admitted 750 such patients. Treatment measures developed at Mill Hill during the five years of war were continued, and several trends were developed further. The unit here consists of 7 separate blocks each containing 50 beds. The staff comprises 9 doctors, 1 vocational psychologist, 1 full-time disablement rehabilitation officer (D.R.O.) of the Ministry of Labour, 1 psychiatric social worker, 1 occupational therapist, and 45 female nurses. The average stay in hospital is six weeks, and only a very small percentage of patients stay a longer or shorter period than this. To date approximately 85% of our patients have been discharged from the Army Category E. Most of the cases were referred to us by the Army psychiatrists of the 45th Division, who handled the psychiatric problems of the 100,000 British repatriates from the European theatre.

Work Therapy

On arriving here our plan was to carry out psychiatric treatment along orthodox lines, but modified to meet the special needs of P.O.W.s. It seemed to us that men who had been segregated in prison camps for up to 5 years would, above all, need help to overcome lack of confidence in their ability to succeed in some job in civilian life. It was decided to try to enlist the help of the working community of Dartford, a town with a peacetime population of 35,000. The manager of the local office of the Ministry of Labour gave every possible help, and by addressing the local Rotary Club and making personal contact with employers, etc., we have built up 41 different outside employments (offering work to a total of 251 men) from which patients may choose. The Ministry of Transport provides three buses, which carry the men to and from work. The emphasis is always on treatment, and the employers show a high sense of social responsibility, trying in every way to help the men to recover their confidence, and not concerning themselves with the actual work output. The men, who are not paid, work for one or two periods of two hours; they are never used in any skilled capacity, but are given an understanding of the whole working of the factory or shop, and simply help where needed or in some department which interests them. If the work does not interest them, or the vocational psychologist recommends a change and their doctor is satisfied that this is desirable, changes may be made once a week. A card index of all the patients and their employment, with the numbers in the various occupations, is kept up to date daily to facilitate changes. The range of choice includes farming, dairy farming, market gardening, building, garage work, various big engineering firms, foundry work, agricultural engineering, shipyard, paper mills, chemical factory, printers, clerical work, and numerous small shops. The big factories offer many specialized jobs—e.g., electrical maintenance, heating, progress, print-room, shipping office, etc.—and the whole programme gives a well-proportioned choice of occupation, representing a fair cross-section of any small community. The patients are visited at their various employments by the vocational psychologist. One nurse is employed full time, going round the places of occupation, straightening out any difficulties with the employers, reporting to the doctor in charge, and noting any absentees. This nurse is one of the most important cogs in the whole machine.

Selection

On the day of admission each patient is interviewed by the doctor in charge and a rough assessment made of his state of health, previous work record, and suitability for occupation. Intelligence tests (progressive matrices and vocabulary) are carried out in every case. If the patient is too ill to work out-

side the hospital he is recommended for handicrafts, carpentry, or gardening within the hospital, selection in such cases being postponed till such time as he is well enough to begin work therapy; the great majority, however, start at once. If the patient has a trade or occupation to which he intends to return after release from the Army, then, so far as is possible, he is placed in an occupation similar to his own. If he does not wish to continue his pre-war occupation, or has no definite trade or occupation to return to, he is referred to the vocational psychologist; he is given appropriate tests, and work therapy is recommended on the basis of the man's own preference, aptitude, and intelligence. This early assessment is to some extent modified by the availability of certain jobs on the labour market—e.g., a man with no particular mechanical ability as judged by aptitude tests, who has done only vehicle maintenance work in the Army, and who expresses a wish to work as a fitter in a garage in civilian life, is made to realize that as demobilization proceeds there will be an inevitable flooding of the market with men much more highly qualified than he; if he still persists in this particular aim he may be advised to try, say, agricultural engineering; if willing he can be placed in such a firm, and the idea put to practical test, while still in hospital. The psychologist takes a close interest in the various employments available to our patients, visiting them frequently, and the limited use of vocational tests is greatly enhanced by this opportunity of seeing the men actually at work; he does not hesitate to recommend frequent change of employment if this seems to be indicated.

Of the 750 patients interviewed so far, 381 intended to return to their former occupation on release from the Army, 173 had a job to return to but intended to seek other employment, 191 had no job waiting for them (56 of these were in the Regular Army before the war), 3 had never been employed, and two were still studying when called up.

Placement

We have been very fortunate in having the full-time services of a disablement rehabilitation officer of the Ministry of Labour. Patients who are likely to be recommended for discharge from the Army see him during their first two weeks in hospital. At the "assessment interview" the D.R.O. investigates fully the man's past work record and discusses his future plans; if necessary he will write to the local office of the Ministry of Labour in the man's home town for information regarding local conditions, etc.—e.g., the local brewery may have been bombed, and what are the prospects for the firm's old employees? There is a second interview ("placement interview") during the patient's last week in hospital; at this all relevant information is made available for the D.R.O. He has replies to his own inquiries from local offices of the Ministry of Labour, and may have obtained aid from other Ministry of Labour sources by using the Resettlement Advice Service (in our case the local resettlement advisory officer helped in many ways on general questions outside the scope of the D.R.O.'s work) or referring patients to the Advisory Careers Section of Appointments Offices, where higher education or training was sought. At the "placement interview" the D.R.O. also has available the psychiatrist's opinion of the man's value on the open labour market expressed in non-medical terms, the information obtained by the vocational psychologist, and the report on the patient's progress at his occupation. So far as is possible the patient's future occupation is made secure before he leaves the hospital.

General Procedures

Routine psychiatric treatment by individual interviews, physical methods of treatment, and social work need not be discussed, as they have followed orthodox lines. Occupation has been dealt with above. Group treatment similar to that carried out at Mill Hill (Jones, 1944) has been continued, with small individual differences, in each of the 7 blocks of 50 patients. One hour is set aside each morning for a meeting with all 50 patients, the nurses, and the doctor. At one meeting a play written and produced by the patients with the help of the nurses, and dealing with some social problem of interest to the group as a whole, is presented; the play may last anything from 5 to 30 minutes, and is followed by a discussion, with as many patients as possible contributing. The doctor acts as chairman,

* Since Mill Hill Emergency Hospital closed this unit is seconded from the Maudsley Hospital.

and withholds any personal contribution until some group solution of the problem appears to be emerging; he then tries to integrate all constructive trends into a viewpoint acceptable to the whole group. We believe that this technique has educational value, and even therapeutic value in some cases. Another day is used for showing documentary films dealing with social problems such as delinquency in children, etc., and these again are followed by a discussion. Two other days are used for explanatory talks on the nervous symptoms which the patients complain of; an attempt is made to give them sufficient knowledge of this subject to enable them to understand adequately their own symptoms. The remaining day is devoted to a general meeting, at which all problems bearing on the running of the block are discussed and dealt with on the spot, so far as is possible, thus eliminating the all too familiar "red tape." In these daily group meetings the patients have every chance of overcoming their isolation and developing a heightened group consciousness. The whole subject has been discussed in detail in previous papers (Jones, 1942, 1944).

All this helps in social rehabilitation, as does the work therapy, where the men come into contact with members of the normal working community. In line with this are the nurses' dancing classes, held at least once a week in each block, and reserved exclusively for patients who are unable to dance and wish to learn. Each block acts as a host to a party of 20 girls from a near-by factory once a fortnight; the men plan this dance or social, and the fact that they are themselves responsible for all arrangements is most beneficial. Approximately once a fortnight the patients stage for the whole hospital a programme of one-act plays or variety, thus maintaining a dramatic tradition which grew up in their prison camps. They produce their own weekly newspaper, now in its 15th number. It comprises 10 foolscap pages, with coloured illustrations, using stencils and an art-silk screen, and is a valuable medium for expression, not only from the literary point of view but also to point out real or supposed defects in the hospital organization. The staff of the *Grapevine*, as it is called (in prison camps the word was used to describe the method by which news was disseminated among the P.O.W.s), also concern themselves with posters popularizing the various occupations, printing programmes for variety shows, etc. The Entertainment Committee meets weekly, and has one patient and one nurse representing each block. The general aim is to give the patients as much freedom as possible in running the unit, to enable them to organize their own leisure activities, and, besides this, to give them ample opportunity to air their grievances, to expect them to provide a solution, which is acted on with the minimum of delay. Any spontaneous self-expression is welcomed, and a patient, if interested enough, may choose to write or paint, etc., rather than follow the organized work therapy. At a less exalted level some patients are allowed to spend their day painting and decorating the wards. Within this loose framework, however, discipline is rigorously enforced. We believe it is essential to show the patients that we are in earnest, and it matters to us that they attend occupation or P.T., etc., 100%. The rule is to give one explanatory warning, and if a second offence occurs the patient is considered to have failed to co-operate fully in treatment, and he is recommended to be posted or treated at a military hospital, where he would come under stricter military discipline.

Discussion

The foregoing account describes some of the activities of this P.O.W. neurosis unit. The procedure would be equally applicable to any group of neurosis patients. Huge numbers of neurotics have been, and are being, discharged from the Forces, and facilities for their treatment in civilian life are quite inadequate. Very few out-patient clinics exist, and the number of beds available for the in-patient treatment of civilian neurotics in the whole of England is almost certainly less than 500. Conditions on the labour market at present are relatively favourable to the neurotic, and, further, he is in most instances protected by the Reinstatement in Civil Employment Act of 1944, which obliges employers to re-engage a former employee on terms not less favourable to him than he would have had in that occupation if he had not joined the Forces. If the employee was in employment continuously for a period of not less than 52 weeks before joining the Army, then the employer is obliged

to re-employ him for at least 52 weeks. As demobilization proceeds, however, we may assume that the lot of the neurotic on the labour market will become progressively harder. Many of these men have potentialities which, if used, would enable them to succeed in some employment: such potentialities cannot be measured adequately by psychological tests alone, although useful information can certainly be obtained; what is needed is the practical test of actual employment under supervised conditions. If certain zones were set up throughout the country and a representative group of employers within such zones given a Government subsidy, the framework necessary for placements would be established. Such firms could then afford to employ a skilled man to supervise, teach, and report on the aptitude, interest, persistence, etc., of men under his charge. Alternatively, the Ministry of Labour might have a training centre in such zones, with the various courses of training available, and the instructors might be used in much the same way as the subsidized firms.

Given such a framework the immediate problem of the rehabilitation of the neurotic to useful civilian employment might be worked out as follows. Existing psychiatric treatment facilities should be maintained so far as is possible. Existing E.M.S. neurosis centres will presumably disappear in the near future, along with the other E.M.S. hospitals. Plans should be afoot either to replace such neurosis centres or to retain such as will be urgently needed. The weakness of replacement is that it may take months or years to organize a really efficient treatment centre, and a tradition which is so important in such a centre does not grow up overnight; a general hospital may be set up on very short notice—it is much more difficult to set up an efficient neurosis centre.

Even more important is the question of nurses: work in a neurosis centre is a highly specialized form of nursing, and neither the general hospital nor the mental hospital training prepares girls for it. In consequence, when neurosis centres were formed during the war they had to start training their nurses in this type of work; if existing centres close and the nurses are disbanded, it will take years to train an efficient team again. In my opinion a neurosis centre without suitably trained nurses is a doubtful asset to the community. If such centres existed for the treatment, selection, and placement of neurotic civilians the most difficult problems could be sent to them; these centres would be in the best possible position to handle such problems, as their therapeutic programme and supervision of the patient's employment could be carried out much more thoroughly than on an out-patient basis. A patient considered unable to succeed on the open labour market could be recommended for sheltered employment after such hospital supervision—few psychiatrists would be prepared to make such recommendation on the basis of out-patient interviews only. Alternatively, complete change of employment might not be recommended, although considered desirable by the psychiatrist or vocational psychologist, because the risk appeared to be too great: at the type of centre outlined such a step could be tried tentatively without jeopardizing the patient's whole future. Briefly, a neurosis centre might be used to separate out the most difficult cases and place them either in sheltered employment (if facilities were made available) or in an employment chosen on the basis of the fullest possible inquiry from psychological, psychiatric, and industrial angles.

Out-patient treatment facilities would have to be considerably increased: existing clinics, if adequately staffed, could be used in the first place, but there would seem to be a strong case for appointing full-time psychiatrists who would be prepared to study the particular problems presented by cases referred from the employment exchanges, and would familiarize themselves with the local industries, factory doctors, welfare officers, works managers, etc.; they would also have to be familiar with vocational selection methods and work in close collaboration with the industrial psychologist. They would use the subsidized firms in their zone for selection and placement in much the same way as would be done from the neurosis centres. Cases needing in-patient treatment would of course be referred to the neurosis centre, which should be fed entirely from these specialized out-patient departments.

It is as yet too early to discuss results from this centre, but a follow-up study is being made by the psychiatric social

worker. One really pleasant aspect of the community here is the popularity of the D.R.O., at group meetings, if his opinion is sought on a technical point his appearance is greeted by cheers gone are the memories of the dole and the Labour Exchange.

I wish to express my indebtedness to Dr. A. B. Stokes, medical superintendent of the Maudsley Hospital who has been father to many of the ideas put into practice here and has helped us in every possible way, also to the people of Dartford who have responded so generously to help the P.O.W.s and to Sgt. Capt. R. G. Henderson, medical superintendent of the Southern Hospital, who has extended to us the fullest possible co-operation.

THE PROFESSION AND THE BILL

MEETING OF BOURNEMOUTH PRACTITIONERS

ADDRESS BY CHAIRMAN OF COUNCIL

A meeting of practitioners members and non members of the Association in the Bournemouth area was held on March 28 when an address was given by the Chairman of Council Dr. H. Guy Dain. The meeting was announced to be held at the Royal Victoria and West Hants Hospital, but the numbers turning up were so large that an adjournment was made to St. John's Parish Hall, Boscombe. Dr. Douglas Granger, chairman of the Division, presided, and was supported on the platform by Sir Kaye Le Fleming, Dr. O. C. Carter, and Dr. Doris Odium. The honorary secretary of the Division, Mr. Ross Smith, mentioned that a public meeting had been convened by the Division in Bournemouth Town Hall on April 10 and that a panel of some 16 or 18 speakers had been arranged to give addresses to rotary clubs, political party organizations, and women's institutes.

A Disappointing Bill

Dr. Dain began his address by saying that present events justified any size of meeting that could be arranged. It was of the utmost importance that the profession and the public should be made familiar with the situation as it developed. They now had before them the Bill of which they had heard so much and thought about for so long. For three years at least they had been considering what form such a service should take, and it was fortunate that there had been time to clarify their ideas on this subject before the Bill was actually introduced. Had the Bill been brought forward two years ago the profession would not have been so well able to deal with it. In the conversations with Mr. Willink they did arrive at a large measure of agreement concerning essential factors, but the present Minister said at first that he was too busy on housing to talk on the medical problem, and when, in the early part of this year, having learned that a Bill was being drafted, the Negotiating Committee asked him to meet them, which he did, he announced that he was not prepared to negotiate with anybody. He was ready to hear comments, not to enter into discussions. Certainly the Bill showed boldness. The Minister had had courage to take a strong line—particularly on the taking over of hospitals—without regard to expected opposition, and now the L.C.C. and other Socialist authorities were parting with their hospitals like lambs. The Minister was to be commended for having seen the wisdom of centring hospital regions on universities, and, in another part of the Bill, for giving doctors some share in administration. He had said that he would expect the miners to have a say in their industry, and he could not deny the same right to doctors.

Nevertheless, Dr. Dain continued, the Bill was most disappointing. It did not co-ordinate the services run by the various Ministries. It did not produce a single health service, but three health services, differently administered and under different management. On being challenged about this, Mr. Bevan said that it was those who worked in the respective services who would co-ordinate them—not a very good answer.

The Future of the Hospitals

The new hospital service, including the voluntary hospitals, would be entirely in the hands of the Minister. Although the

Minister had said that there would be private beds it might well happen that in some areas, under pressure for public beds, the private accommodation would be taken over, and consulting physicians who did private practice would find great difficulty in continuing it owing to lack of private bed provision. It was not difficult to see that before long certain physicians and surgeons would be whole time salaried servants of the State. The Minister had not laid down the constitution of the Regional Boards who were to administer the hospitals, though he had laid down the constitution of the Executive Councils. His explanation was that the constitution of the boards might vary with the region, some regions being predominantly voluntary and others predominantly local authority. But it would be easy under the Bill for the boards to become almost entirely local authority. One interesting word in the White Paper was "initially" ("each board will be composed of people... including, initially, those with experience of the voluntary hospital system") (para. 20)—suggesting that presently the initiative and character of the voluntary hospitals would be destroyed. The appointments to hospitals would be made by Regional Boards. It was true that the terms of service of specialists as well as consultants would be arranged centrally, but there would be an alteration in the relationship between the staff and the hospitals: the staff would be appointed to the regional service and not to the actual hospital.

Public health provisions in the Bill left the situation very much as it was now, except that compulsory vaccination was abolished.

"Direction"

The proposal to abolish goodwill in practices involved serious considerations. The attitude of the B.M.A. had been that there was no need whatever compulsorily to distribute doctors. In so far as there was inequality of distribution between areas it was largely because some areas could better afford to pay for doctoring than others, when provision was made in a State service for everybody then doctors would rearrange themselves more naturally in places where their living could be earned. When National Health Insurance came in there were great alterations in the number of doctors willing to work in closely populated town areas. The Central Medical War Committee had elicited that it was very misleading to say of a particular area like Bournemouth that on the basis of total number of doctors to population it was over-doctored because such an area contained a large proportion of elderly doctors: doctors retired or on the point of retirement and undertaking only a relatively small amount of work. The profession was prepared to see, without resorting to compulsion, that there was a proper distribution to fill the gaps.

Mr. Bevan had realized that the measure of direction imposed in the Bill would upset the value of practices, and therefore, in return for the abolition of goodwill, the compensation proposals were put forward. The Minister had been informed by the Association that it had no power to enter into an agreement with him on this subject, that the Representative Body had declared itself opposed to the abolition of sale and purchase. Without compromise on the principle, however, there had been consultations between the actuarial and statistical experts of the Association and the Government actuaries, as a result of which the global sum of £66,000,000 was reached. It was a lot of money for the country to find in return for nothing whatever of value to the State, and it represented no gain to members of the profession who would receive a corresponding sum in the ordinary course of events.

One point to bear in mind was that the compensation would be received on death or on retirement or in exceptional cases where a practitioner was seriously in debt for the purchase of his practice. He also referred to the penalties which attended any attempt to sell supposed goodwill after compensation. If a practitioner attempted to sell his house to his successor in the practice at more than its proper market value after compensation had been received it would be an offence for which there was a prescribed penalty. One point about compensation was the effect it would have on partnerships. They were all agreed that it would be a great advantage for practices to be conducted in groups and partnerships, but

with monetary considerations taken out of the partnership agreement it was questionable what was going to hold partnerships together. These proposals would break up partnership practice rather than encourage it.

Objections to Basic Salary Payment

No statement was made in the Bill as to the method by which doctors were to be paid. The White Paper (para. 46) spoke of a combination of salary and capitation fee.

"We have said much in the past about free choice, but perhaps have never properly appreciated its full significance. It was one of the cardinal principles of our predecessors in 1911. There are people who say, 'Yes, but there is not much free choice anyhow. In lots of areas there is only one doctor. So why bother?' But free choice involves a great deal more than that. Now that the whole population are in the scheme it is of the utmost importance as affecting this principle how doctors are to be paid. If paid by salary they become the servants of the people who employ them. If paid by capitation fee or per case they are in an entirely different position; they are not paid servants, they are contractors contracting with the Government to do a certain job."

If all doctors were paid by salary and those of about the same age got the same sort of salary the Government would naturally want to see that they did approximately the same amount of work, and the result would be that doctors less acceptable to patients would have patients allocated to them. The progress of the doctor in his profession should depend on the patient's choice and not on the good will of senior officers. The moment they accepted a part-time salary they were on the slope. If the profession was to escape the thralldom of a civil service the general practitioner must in no circumstances be paid a salary. "We may have an enormous fight for this, but it is an essential freedom of the doctor for which I hope we are prepared to stand." (Applause.)

The disciplinary machinery under National Health Insurance had on the whole proved satisfactory, thanks to the safeguards on which the profession had insisted, but Dr. Dain was convinced that that machinery would not be sufficient when the whole profession was included in the service. There should be some sort of appeal beyond the Minister. Another matter of insistence should be that every registered doctor had the opportunity to earn his living. A practitioner might find himself refused permission in area after area. Again, in the Bill there was nothing to protect the civil rights of the practitioner, it might be held that a doctor, because he received money from State funds, must not sit on the local council or in Parliament. No such restriction could be tolerated.

Future Action

In concluding his address Dr. Dain said that if the Bill as it stood should go through unaltered he hoped and expected that the profession would say that it would not accept service. The utmost endeavour should be made during the ensuing weeks to arrange for public support to be enlisted on behalf of those cardinal principles which the profession had laid down. In this way it was possible to influence the Government notwithstanding its Parliamentary majority.

"I have great hopes that we may secure the modification of the Bill very materially. After all, it is up to the Minister to provide a service for the country, and he cannot provide a service for 100% of the people unless he has 100% of the doctors. That fact alone may lead to the consideration of the sort of modifications which the profession would accept.

"When the final shape of the Bill is known it will be the responsibility of the profession to say whether it accepts service."

Various Points of Criticism

When the meeting was thrown open for questions one member pointed out the contradiction in terms whereby it was stated in the Financial Memorandum that the service would cost £152 million, and yet the remuneration of doctors had not yet been decided. Was it an unfair inference that the Ministry had worked out the figures and was prepared to get a cheaper service if it could? Dr. Dain said that something of the estimated amount for general practitioner service could be gathered from the figure of £45 million for that service,

together with pharmaceutical, dental, and ophthalmic services, this for a population of more than 40,000,000. Until the Spens Committee report was published it was not known what the general practitioner service was going to cost. One thing about the remuneration under the new service was that there must be an end of those continual representations to the Ministry which had marked the thirty years of the National Insurance Act. There must be some equivalent to the Wages Boards in industry.

One questioner asked about compensation for specialists. Dr. Dain said that in certain areas eye specialists and in some cases ear-nose-and-throat specialists had been in the habit of buying and selling their practices, and this point had been put to the Ministry. "It struck the Ministry with great horror that this question should arise in another place, but they said that they were not interfering with that aspect and that these specialists could go on buying and selling their practices as they pleased."

He explained in answer to other questions how the £66 million compensation figure was arrived at—on the basis of two years' purchase on 1939 values plus a betterment factor of 16%, or of 1.9 years' purchase plus a betterment factor of 22%. The amount was held to apply to 17,900 practices. Asked what was the position of those not in practice in 1939, Dr. Dain said that they would have to furnish evidence of their present practice. Obviously it would be necessary to set up local tribunals.

A member wanted to know whether there was anything in the Bill to protect clinical freedom. Dr. Dain replied that there was nothing which impaired it except in so far as loss of practice goodwill, institution of a certain amount of direction, and a part-salary basis might be held to do so as pointing to complete employment by the State. Another asked about the future position of the B.M.A. as the body speaking for the profession. Dr. Dain said that the Association had such a variety of interests and occupations that when this service was started, in whatever form, the importance of the Association in upholding the interests of men and women serving would be greater than ever. One young practitioner said that large numbers of recently demobilized doctors would be tempted to go into the Government scheme for economic and security reasons. Dr. Dain said he realized that there was a large group of people in that position, but he hoped they would not be tempted towards taking the easy way. The Association was constantly being asked for advice on this subject, and it urged that no practitioner should cheerfully consider the prospect of taking on a job at a salary which would make him the servant of the State for life.

Part-time Service

On the question of part-time work in a national service, which was a difficulty to more than one speaker, Dr. Dain said that doctors would be free to take private work except that they must not take on as private patients persons for whom they had accepted responsibility as public patients. It was no exaggeration to say that at present no two doctors in private practice were doing the same amount of work for exactly the same number of people, and while there was variety in the number of people to whom a doctor gave service and in the amount of service he was required to give, there would be no such thing as a whole-time job. Of course, his list must have a ceiling, but that would not act to any extent in cutting out private practice, except for a very few people.

In reply to other questions Dr. Dain said that he hoped members of the Association appreciated how fully and promptly Headquarters had acted, both in putting over the Association's case to the public and in informing the members of the profession themselves. (Applause.) This had been a feat of great magnitude for which Dr. Hill was largely responsible. He also referred to the setting up of the Guarantee Fund. There was nothing "phoney" about it, and while it might never have to be used, beyond a certain part of it for expenses, it might, on the other hand, prove of the most vital importance. He mentioned that a number of subscriptions had been received from the laity. The patient of one doctor, having ascertained from him that he proposed to subscribe his £25, said that she would add £25 to his and make it £50.

Back to 1911

Sir Kaye Le Fleming said that that evening he was strongly reminded of the time when he was chairman of that Division and the National Health Insurance Bill was under debate. There were crowded meetings of the profession in that town, and 95% of the profession pledged themselves to refuse service unless certain terms were conceded. In the end the terms offered were not satisfactory in the view of 95% of the profession and yet the remaining 5% were able to split the profession and enable the Government to get what it wanted. The present Bill was brought forward by a Labour Government sustained by a large Parliamentary majority and was the first fruits of a pledge to introduce a whole time salaried State service. The small amount of direction in the present Bill would lead eventually to every doctor in the country being under direction. He described the forces they had to meet including groups in their own profession who favoured such a service. The character and extent of those forces must not be underrated. He deprecated a false optimism. He wanted to see the profession united on the things on which it could be united in a dignified way and putting aside those issues it could not successfully further because of its own disunion.

We can all agree on the principle of voluntarism, we can all agree in opposition to direction and I should like to see the profession take the stand that this Bill is bad for the public for this that, and the other reason but that we are likely to be steam-rollered by political and economic factors which we are unable to resist and that it is the public who must save themselves and our profession they must not look to us to save them. I hope that at the Representative Meeting we shall abstain from bickering over small points and concentrate on the big principles on which we can all stand united." (Applause)

Dr Dain said that he hoped they would not be too depressed by what Sir Kaye Le Fleming had just said. It was true that in 1911 many people said they would not accept the terms, but the issue then was only a question of how much money was to be available for the remuneration of practitioners. The Association at the time of the passing of the National Health Insurance Act had already gained the cardinal principles for which it had stood—that the profession should not be employed by local authorities or by friendly societies, that every practitioner should have the right to take part in the service, that the patient should have free choice of doctor. All those things had to be fought for and secured. It was only on the money that they seemed to founder at the end. The *Westminster Gazette* of that day, at the end of the fight, said that the ordinary Englishman by tradition did not know when he was beaten, but the B.M.A. did not know when it had won. "We have to stand now for public freedom and for our own freedom, and I think we shall be brave enough to do both" (Applause)

He added that he hoped at the forthcoming Representative Meeting they would not attempt to tinker with the report already placed before them by the Council, but would support the Council by an overwhelming vote in the maintenance of the principles set out. It was hoped that there would be a good "second reading" debate in the Representative Body, and that the volume of support in reaffirmation of what had already been decided would impress alike the public and the Government.

Dr O. C. Carter, in proposing a vote of thanks to Dr Dain, said that the Chairman of Council had shown a masterly grip of the whole subject. He was a pillar of strength to the Association, and if at the periphery they did their job as well as he did it at the centre they would not only save themselves but save the future of medicine.

The Ministry of Health has published as a pamphlet, with specimens of printed material, particulars about immunization against diphtheria, giving guidance to local authorities for planning and carrying out campaigns for the protection of children. The main emphasis of the campaign is now on immunization of children before the age of 1 year. Publicity material available to local authorities includes press advertisements, posters, cinema slides, and leaflets for use in conjunction with personal persuasion by doctors, health visitors, teachers, and voluntary workers. The Minister hopes for a planned campaign in the coming spring and summer months.

PUBLIC OPINION

THE PRESS AND THE BILL

Press comment on the National Health Service Bill is inevitably divided, and division is most marked along the lines of political cleavage. Reading from left to right the *Daily Herald* (March 22) appeared to be thinking wisely.

"It is true that the medical profession becomes partly a public service. That proposal, we believe will not meet with the opposition from the profession which the Tory Central Office might desire."

"It is not true that patients and doctors are to be robbed of their rights. These bogies find no place in the Bill, and after a few weeks of discussions we prophesy that the diehard campaigners will be hard put to find an argument."

The Contemporary Pattern

The *News Chronicle* (March 22) welcomed the Bill as a bold and enlightened measure, and commented:

"The new Bill fits into the contemporary pattern of social legislation, and to oppose it would be like trying to halve the tide."

"The doctors too will have a great measure of freedom under the new scheme if they care to exercise it. The close personal relationship between doctor and patient will be maintained. Indeed, the transition from private to public treatment of patients is to be made as painless for the doctors as possible, and the advantages which they will enjoy under the Bill will be obvious at least to the younger and more progressive members of the profession."

The *Daily Express* (March 22) described the Bill as "a vast extension of the panel system supplemented by a State-run hospital and specialist service, and added:

"It squeezes and reduces the private practice of medicine and surgery with its confidential and unique relationship between doctor and patient."

And it will turn most doctors into full time or part time State servants dependent for their livelihoods on the satisfaction the State, not to their patients, but to the State.

The power of the citizen to see that his local hospital is efficiently run is taken from him.

Finally the doctors themselves. They bitterly resent the attempt to manoeuvre them into becoming civil servants. They ask, "What have we done to deserve this?" They sense a reflection on their calling, a suggestion that they have failed in their duty to the public.

Injustice and Regimentation

The *Evening Standard* (March 21) took, if anything, an even stronger line, viewing the Bill as "a heavy blow to the age-long tradition of personal relationships between doctor and patient."

"Theoretically all are free to choose their own doctor at the Health Centres, but in effect practitioners are to be encouraged to pool their remuneration with the aim of 'eliminating competition for patients.' Where fees are pooled, how long will it be before patients become subject to the same inhuman system?"

"As a fact, the Bill is a first step towards the full time employment of doctors as State servants. Doctors returning from the Services or newly qualified cannot found new practices; they are to be directed. The doctors, moreover, threatened by compulsory State service, liable to direction and allowed neither to buy nor sell their practices—for some reason this does not apply to dentists—do not even know what rate of remuneration they will receive. It is not hard to imagine what answer would be given to such treatment by the miners, for instance."

"Soon the Bill will come before the House. It will be fought by the doctors. It should be fought by all who detect injustice and regimentation."

According to the *Daily Sketch* (March 22) "this Bill is the apotheosis of red tape. It threatens the independence of the general practitioner. The doctors have a justifiable dread of becoming salaried Government servants."

"The doctors object to being directed to districts where they do not want to go. They rightly demand freedom of choice. The varying salaries offered in 'under-doctored' areas constitute an attempt by the Minister to induce doctors rather than to direct them. The goodwill of a practice will in future no longer be owned by a doctor. One more wedge in their independence."

"It is not a good thing for doctors' fees to be pooled, it is not a good thing for the sale of practices to be forbidden. It is a bad thing that hospitals established for the special benefit of religious denominations and other bodies should be deprived of their specific and original intentions."

"The net cost to the State of this scheme will be an annual one of some £95,000,000. The compensation payable to doctors under

the scheme will cost at least £66,000,000. In the face of all our commitments, is not this equivalent to sheer lunacy?"

Circumscribing Independence

The *Scotsman* (March 22) made two most important points: that "in the long run doctors will become full-time salaried servants of the State"; and that professional freedom and responsibility for patients will be impaired."

"Although the Bill seems to offer a certain amount of flexibility and freedom of choice to the public and to doctors, it is not likely that a vast State scheme will be long in operation without bringing about radical changes in the personal relationship between doctors and patients or without circumscribing the independence of practitioners in professional matters. A national health scheme of a less revolutionary nature and more widely acceptable might have been formed by the extension of present services, such as bringing the dependants of insured persons within the scope of National Health Insurance, and by more co-ordination of hospital facilities."

"Such financial estimates as are given make it clear that the scheme will be a heavy burden for the State. That might be borne if there were more assurance that it would result in better medical treatment and improved public health services, but the scheme involves such far-reaching departures from traditional methods that it inspires more uncertainty and doubts than confidence."

Serious and Seductive

The *Daily Telegraph* (March 22 and 23) in successive leading articles pointed out that the Bill "sweeps away many admirable things."

"The selfless devotion of doctors in giving their services to hospitals will apparently become superfluous. The appeal to the charitable public—the response to which used to be a fine feature of our national life—must be lessened."

"Though it is undoubtedly right that access to the means of the prevention and cure of disease should be the same for rich and poor alike, it remains to be seen what will be the effect on the national character and spirit of having everything for nothing—or at least for nothing except the persistence of a crushing rate of taxation. Nevertheless, the weight of argument is on the side of the new order which the Bill seeks to create."

"Ostensibly the principle of freedom of doctor and patient is . . . honoured. In fact, it seems almost certain that private practice in the existing sense will gradually die out; but it will not be arbitrarily exterminated."

"The broad conclusion is that within the limits of the agreed principle that there is to be a national health service, Mr. Bevan has deduced a serious and in some respects seductive scheme. On many details judgment must be reserved for full consideration, but it does not raise party issues, and it must therefore be hoped that I consider objectively amendments when they are presented in due course. What we all want is a service which will lessen both the prevalence and the ravages of disease; and the onus is on Mr. Bevan to show that his proposals will secure it."

"But it is difficult to believe that the objection of the medical profession to a scheme which will in due course turn its members into State-employed civil servants will be softened within the next few weeks, and equally difficult to believe that Mr. Bevan eased the way when, as Dr. Dain states, he refused in any sense to negotiate with the doctors."

This Splendid Venture

The *Manchester Guardian* (March 22), warning of reefs ahead, said that "... the principles of democratic responsibility and professional guidance are confused. The Central Health Services Council remains, but the inclusion of *ex-officio* members who can only regard themselves as delegates of sectional interests will detract from its influence and authority," and went on:

"Not only will doctors be free to stay out and practise privately (as, indeed, they should be); they would also be allowed to take private fees from patients who have already paid in taxes and insurance contributions for treatment by them as participants in the public service. The dangers of this provision were recognized in the Coalition White Paper—which could suggest no means of guarding against them—as well as in the Labour Party's critical commentary. The plain fact is that no safeguard is possible."

"Poor patients will claim their rights and be convinced that they are getting an inferior service; rich patients—and many others who cannot really afford it—will insist on paying fees in the expectation of preferential treatment, and will go elsewhere if they do not get what they are paying for. This, in short, is a false freedom that can only survive to the extent that it is abused. It must inevitably poison the doctor-patient relationship. It is the reef on which this splendid venture, with all its prospects for development, might founder at the outset."

Bitter Medicine

The *Times* (March 22) commented: "The Government have wisely decided not to force a salaried service upon general practitioners, but to combine a basic salary with capitation fees in variable but as yet unknown proportions. They have also had the courage to put an end to the sale of publicly remunerated practices, a reform now probably supported by at least half of the medical profession." And on the proposed hospital services:

"If it is right to-day to transfer the municipal hospitals to regional authorities, as the Coalition White Paper advocated with some vigour, it cannot be wrong to transfer the voluntary hospitals too, even though, in the absence of permanent authorities intermediate between local and central government, this transfer in both cases involves vesting the legal ownership of hospital buildings in the Minister of Health. It cannot be wrong, yet it may be unwise. The dangers are obvious enough—rigidity of central control, stifling of initiative among doctors, weakening of contact between patient and hospital management, discouragement of voluntary personal service. But Mr. Bevan's solution of the hospital problem is at least as good as any alternative yet propounded, and his system could be kept free of these obvious evils. It could in fact be so administered as to permit the rapid development of a well-knit yet flexible hospital service throughout the country, with a spirit of healthy competition between the regions."

"Mr. Bevan is aware of the dangers of excessive centralization and of the need to draw all branches of the medical and allied professions into the work of planning and administration. His solution is far from ideal, and for many it will be bitter medicine. Some doctors will be attracted to it because it offers them freedom from control by local authorities and gives them wide opportunities for team work and participation in operating the service, though others will argue that these ends can be attained by other means. In spite of its drastic administrative simplifications, the Bill leaves many problems of co-ordination to be tackled. But the question to be answered is how the teams of skilled men and women who are the hospitals can best serve the community."

Not Civil Servants?

The Sunday press showed just as great a variety of opinion. *Reynolds News* (March 24) claimed that the Bill "meets the doctors more than half way, offers them compensation beyond their dreams, visualizes a condition of things in which medical service would really be the highest form of service, and answers every canon the B.M.A. has ever issued."

"It is indeed too soft in its handling of the professional propagandists who put out the B.M.A. case and overlooks the well-known fact that the B.M.A. ballot of the doctors showed them to be already in favour of such a service as this. The public will do well to understand what they are being offered, and individually and collectively must make it clear to the doctors that this service cannot be sabotaged by any section, however influential."

The *Sunday Graphic* (March 24) wrote: "You cannot make men humane by Act of Parliament; and every step in State regimentation makes less possible the private and personal relationship which should exist between doctor and patient." The *Empire News* (March 24) suggested: "Surely it would be wise to concentrate first on providing greatly improved housing conditions, for squalid, overcrowded, and unhygienic homes will undo the advantages of the most utopian health centre." The *Sunday Chronicle* (March 24) wanted to know: "Is one man entitled to antagonize the majority of a medical profession which firmly believes that so complete an autocracy must lower the standards of our present health services? Can one man—however well-intentioned—avoid the mediocrity that must follow the regimentation of our doctors into the ranks of our Civil Service?"

According to the Political Correspondent of the *Observer* (March 24): "Mr. Bevan has his answers ready, and believes they will be found convincing. . . ."

"Those who enter [the Service] will not rank as civil servants, in spite of some loose talk on the subject by Right wing critics of the Bill. Their contracts of employment will be . . . not directly with local authorities or the State. Hence they will retain all their ordinary rights of citizens, including the right to stand for Parliament."

Doctors "will be 'State-salaried' only in a limited sense, for the larger part of their remuneration will often come from capitation fees, dependent on the number of patients they attract."

"The basic salary for a young doctor may not be more than £400 a year, with local variations, but capitation fees may be high enough

to enable them to turn up to £1,000 a year at a quite early stage in his career.

The *Strait Times* (March 22) resented four freedoms—Freedom for patient and doctor to come into the new service, or stay out; freedom for people to choose their own medical advisers; professional and scientific freedom for the doctor; and the free relationship of confidence and intimacy between doctor and patient under the State system or a private practice.

The question is not whether we could have a comprehensive national health scheme or no such scheme. It is rather the logic of Socialist doctrine given the opportunity of a common effort to raise the standard of public health service and its bitter conclusion of a completely reorganised and national State service, or whether the four essential freedoms for doctor and patients are to be preserved within and alongside a comprehensive national health system.

History and Sentiment

Of the weekly papers the *Spectator* (March 29) in a careful review of the Bill observed:

The new Bill does much too far towards meeting the doctors' objections for any such hostility. One reasonable fear, at a time when the Coalition Government's proposals were under discussion, was that the doctor would find himself the paid employee of some local authority, responsible ultimately to a bureaucracy in Whitehall and with neither the knowledge nor the sympathy to make its administration tolerable. The outstanding feature of the present Bill is the extent of the share of administration accorded to the profession at every stage.

The Bill, of course, is susceptible of improvement perhaps of substantial improvement. The relation of private practice to public service, and the method of a doctor's remuneration, partly in the form of basic salary, partly of capitation fees are matters which must be fully discussed inside and outside Parliament. So much more must the vitally important section of the Bill which deals with the hospitals. Here sentiment, so far as the voluntary hospitals are concerned, points one way and practical considerations the other. There is nothing more admirable in national history than the voluntary hospitals record of service, but the voluntary hospitals have become hopelessly inadequate to the needs of to-day and most of them are in financial difficulties. Hospital accommodation as a whole falls deplorably short of the need, the waiting lists of sick and suffering are a blot.

If nothing but mere efficiency were in question this plan would stand approved, but history and sentiment have their place, and it is by no means certain that the nationalization of the voluntary hospitals is essential, effective co-ordination and satisfactory financial arrangements may well be attainable without that. If the Government is wise it will give ample time for the discussion of this, as of many other arguable provisions of the Bill. If the doctors on their side are wise they will set themselves to secure by reasoned amendment what they could never achieve by flamboyant opposition. They will get full public support in that.

According to the *Economist* (March 23) "No doubt the B.M.A. may find provisions which are incompatible with the 'freedom of the medical profession,' but it is difficult to see how, if a national health service is to be established at all, more professional representation could be given and greater deference be paid to the doctors' objections. The chief losers under the new Bill seem, at first glance, to be the local authorities. All of them will lose their hospitals, and the minor authorities will lose their present health functions, such as maternity and child welfare, to the counties and county boroughs. Even if Mr. Bevan succeeds in disarming the doctors, the progress of the Bill may not be easy."

The *New Statesman and Nation* (March 30) asked:

"What do the doctors want? That nobody yet knows, though we shall probably know a good deal better before Mr. Bevan's Health Bill gets into operation. Substitute, then, a less unanswerable question: What does the articulate minority that has taken charge, so far, of the doctors' case want and hope to achieve, by the line it is taking up in relation to the Bill? It cannot be simply more money for the profession as a whole, there is every sign that the Government means to leave the B.M.A. with no plausible ground for complaint on that account. Money, of course, does enter into the question."

To state this is enough to make it clear that money plays only a small part in the present case of the doctors against the Government—though it may have played a larger part at an earlier stage, before the generosity of the Government's financial intentions had been made known. These other grounds are usually stated in terms of vigorous objection to bureaucratic control and especially to control by local authorities, and they are often summed up in an

objection to salaried, as opposed to fee-getting, practice. To many doctors—even to a good many panel doctors—a salary free, like a professional come-down in comparison with a fee, or even a capitation fee. It seems somehow to be less 'professional'."

"Now this, when one comes to think about it, is rather a range. In the higher ranges of the teaching profession it is just the other way round."

"It is not, of course, entirely a matter of salaries *versus* fees. If it were, the prejudices of the traditionalists would hardly make headway against the desire of many of the younger doctors for a chance of a good secure income without any need to put down (probably borrowed) capital in order to buy a practice. The fear of bureaucracy is also real, and would be worthy of respect if there were in fact any danger of it—or, at any rate, of more of it than is reasonably involved in any plan to provide a comprehensive medical service for the people. But, as the Government's Bill stands the danger of bureaucracy, national or local, has surely been reduced to a minimum."

"Many young doctors are Socialists, and start out from a quite different set of assumptions about what is right, but most doctors of senior standing are not Socialists—far from it—and will take the class system for granted as the basis of their thinking."

Not Far Enough for Him

Three individual views, received prominently in the *Observer* (March 24) Lord Horder concluded a balanced survey of the position in these words:

"The doctor can, and must, make this seemingly rigid structure flexible, he must make these dry bones live. But he must control the machine, he must not let the machine control him. For a doctor's work is as he does it, not as a system dictates it should be done. The glory of any free man's work is that it is an expression of himself rather than of a system. The doctor has changed much in things that are immaterial since he earned R. L. Stevenson's fine encomium. He must, and I believe he will, continue to deserve that it be said of him that he 'most notably exhibits the virtues of the race.'"

Dr. H. Guy Dain writing in the *News of the World*, asked: "Will you be satisfied with a health service which places you and your doctor under State control? The best and most complete health service does not require this; indeed, it would not be best if it interfered with the real doctor-patient relationship."

And last but by no means least, Prof. Laski (quoted in the *Daily Telegraph* of March 25) said: "Mr. Bevan's National Health Service scheme did not go far enough for him. He would have abolished private practice. He described as pre-Adamite the economics of the British Medical Association."

SALARIES OF NURSES AND HOSPITAL DOMESTIC STAFF IN NORTHERN IRELAND

Three committees and a co-ordinating council have been set up in Northern Ireland to review and report on the salaries and conditions of service of nurses and hospital domestic staffs. Their duties will be similar to those of the Rushcliffe and Taylor Committees in England and Scotland and the Joint Council for Hospital Domestic Staffs in England. The first committee will be concerned with general nurses, under the chairmanship of Mr. C. J. A. Woodside, the second with mental nurses, with Dr. T. Carnwath as chairman, and the third with hospital domestic staffs. Dr. N. B. Graham will act as special medical adviser to the mental nurses committee. The members of each committee form two panels—one representing employing authorities and the other employees. The co-ordinating council will include the chairmen of the three committees and two members nominated by each panel. The action of the Minister in establishing these committees has been generally welcomed and it is hoped that preliminary reports on urgent matters will be presented to him before the summer.

Local authorities are asked, in a recent circular, to submit to the Minister of Health proposals for improving hospital accommodation generally, but especially for nurses and domestic staff, and for providing domestic facilities which would make their work easier. Proposals, which should cover the needs of the next five years when it will be impossible to build new hospitals, should be listed in order of priority, first place being given to those which help hospitals to recruit and retain nursing and domestic staff. Schemes already, before the Ministry should be included, and the estimated cost given where this has already been arrived at. It is thought that there are probably a number of alterations not requiring much building labour which could well be attended to now and which would add considerably to the efficiency of the hospital.

Reports of Societies

VASCULAR INJURIES IN WAR

At a meeting of the Section of Surgery of the Royal Society of Medicine on March 6, with Mr. E. F. FINCH in the chair, the subject for discussion was "Vascular Injuries in War."

Mr. MASON BROWN based his remarks on an analysis of a number of cases, British and Italian, dealt with at a surgical centre in Italy in 1944-5. Arterial wounds, he said, should be divided into two main classes: (1) those associated with great soft-tissue damage requiring urgent surgical treatment (in many such cases amputation should not be regarded as a confession of failure, but as the price paid by the patient for life-saving surgery), and (2) those associated with trivial wounds of entry and little or no external haemorrhage, but with haemorrhage into the tissues. The treatment adopted in the cases admitted to the centre, which included 78 cases of traumatic aneurysm, was influenced by the results of primary ligation. In early cases sutures were carried out if this was at all possible. The ischaemic limb was kept at rest in a cool environment, using antiseptics during the summer months, and in a position which gave the maximum circulation—slightly elevated if there was oedema, but otherwise slightly dependent. Penicillin was employed liberally in the control of infections in the associated wound and in any wound distal to the lesion. Except for certain indications, such as external haemorrhage and secondary haemorrhage, no operation was carried out before the collateral circulation had been developed.

The operations—62 in all—were as follows:

Emergency operations (23): direct ligation 16; arterial suture 3; proximal ligation 4.

Operations on minor vessels (14): excision 9; quadruple ligation; arterial suture 1; aneurysmorrhaphy 1.

Operations on main vessels (25): arterial suture 11; aneurysmorrhaphy 1; direct ligation 11; ligation of fistula 1; ligation of neck of sac 1.

There was one death from ligation of the common iliac artery; in only two other cases were there complications. He added that a military surgeon could give only immediate results, and there must be a long-term follow-up. He hoped that this might be possible, in the British cases at least. Among the conclusions which seemed justifiable were: that the treatment of arterial wounds with minor soft-tissue injuries should be

conservative; that the nature of the operation to be carried out should be decided only when the exact pathology had been disclosed at operation; that, in the absence of emergency indications, operation should be delayed until the collateral circulation was established; and that the care of the ischaemic limb was of the greatest importance.

Effects of Sympathectomy

Mr. A. M. BOYD recounted his experience at the 63rd General Hospital, Cairo, 1942-5. For one reason or another he ligated 41 main arteries. In the war of 1914-18 Makins had shown that in a high percentage of cases gangrene followed ligation of the main vessels, but, apart from the presence of gangrene, there were other distressing complications—ischæmic necrosis followed by fibrosis, nerve palsies from poor blood supply, wasting muscles, and, last but not least, intermittent claudication. Makins had stated that ligating the associated vein was of assistance in maintaining the collateral circulation, but one could not help feeling that ligation of the vein could produce no more effect than the damming back of the venous flow, and that could be done equally well by posture. Moreover, ligation of the vein could produce a syndrome which was extremely disabling. The site of the ligation of the artery was important. But the main point he wanted to bring forward was the question of sympathectomy. With arterial lesions this was the quickest method of dealing with collateral circulation, though there was a certain amount of prejudice against sympathectomy, largely on account of physiological teaching. There was powerful evidence that sympathetic block did dilate the arterial tree. In 41 ligations of the main vessels he had carried out the appropriate sympathectomy in all but one case. In this series there was one case

of gangrene, which he thought was due to operative error and the sympathectomy could not be blamed. Cases of arteriovenous aneurysm numbered 15; their location was extremely difficult.

Prof. J. R. LEARMONTH mentioned the work of the vascular centre established under the E.M.S. in Scotland. In one case in which a large aneurysm of the first part of the subclavian artery extended into the superior mediastinum a very mutilating operation was necessary before it was found, and it was a matter for gratification to find that there remained little or no impairment. Many patients with arteriovenous fistula had blood changes not completely recognized. In addition to an increased blood volume they had a relative polycythaemia and an increased load of haemoglobin in each corpuscle. Several cases had come their way in which a vascular tumour had followed injury. In some of these, but not in all, there had been a small cutaneous haemangioma, and that lent support to the view that haemangiomas as a whole were not true tumours, but merely aberrations from the primitive arrangements of the vessels.

Dr. F. ALBERT, professor of surgery at Liège, said that his own experience dated from the last war, since when he had been continuously interested in all aspects of the surgery and pathology of vascular lesions. One of the points he emphasized was that simple obliteration of the main blood supply of the limb, whether by localized compression or ligature, did not produce any vasoconstriction, but did produce an important degree of vasodilatation and entailed a fall in blood pressure, which became more and more marked as the experiment proceeded.

A preliminary follow-up of 34 patients at Park Prewett Hospital, Basingstoke, was presented by Mr. MAYER. The cases included 17 varicose aneurysms, 11 false aneurysms and arterial haematomas, and 6 aneurysmal varices. There were no deaths, no cases of gangrene, and only one case of ischaemic myositis. Cure by operation was effected in all cases except one, which was improved. Ligation was performed on 26, and suture on 6; of these 6 suture cases, 3 were completely successful, 1 partially successful, and 2 failed.

Mr. F. A. D'ABREU said that Makins drew attention to a condition which he called arterial shock, due to injury which, without actually tearing the artery, resulted in intense spasm of the artery and its collaterals. A man in Burma had a penetrating wound in the upper arm, followed by absence of pulse and quite cold hands. Arterial injury was diagnosed, but on arriving at the neuromuscular bundle no sign of the brachial artery could be found. After careful exploration he discovered a vessel no larger than a quill which had no pulsation in it. On dissecting this tiny vessel he was able to see pulsation return into it; the wound was closed, there was no haematoma, and the condition of arterial spasm completely disappeared. The man was evacuated in good condition.

Mr. A. W. BADENOCH stated that he had had the opportunity of seeing a number of cases of vascular injury, including injuries of the carotid. He himself saw several cases of ligation of the common or internal carotid, and in none of them was there any hemiplegia or other ill effect from the ligation: none of these cases had had a sympathectomy. Another speaker had had the same experience, and said that a series of over 100 cases of traumatic aneurysm had been dealt with at one centre without a single instance of gangrene, and in no case was sympathectomy done.

A clinical meeting of the Medical Society of the L.C.C. Service was held at Bethnal Green Hospital on March 6, when cases were demonstrated by the staffs of Bethnal Green and Hackney Hospitals. There were 90 members present. After the demonstration there was discussion upon some of the cases, including the use of silver filigree for operation upon herniae.

The Microbiological Panel of the Food Group of the Society of Chemical Industry held five meetings during the past year. The subjects of the eight papers included fungicidal action of copper; heat-resistance of micro-organisms; problems in the bacteriology of rivers; some aspects of disinfection; and amino-acids and the metabolism of the cell. The annual general meeting of the Panel will be held on April 12 at 2.15 p.m. at the London School of Hygiene and Tropical Medicine.

Correspondence

The Health Service Bill

SIR.—There is an aspect of this Bill which so far has received little attention but which, to me, appears to be of supreme importance to every citizen. I have examined the Bill and it looks to me uncommonly like the first step, and a big one, towards National Socialism as practised in Germany. The medical service there was early put under the dictatorship of a "Medical Fuehrer." This Bill will establish the Minister of Health in that capacity. I mention only a few of the signs that this is the intention. Camouflaged by the existence of the Central Health Services Council, ostensibly intended to help the Minister to co-operate with the medical profession, he can suppress its report if he disagrees with it instead of presenting it to Parliament. He is to be responsible for all our hospital and all the medical and nursing services. He is to control by Regulations all appointments made by the Regional Hospital Boards. Through the Medical Practice Committees he can include, or exclude, any new applicant for practice in any area. If he is not satisfied with the conduct of any board or committee he may transfer their functions to himself.

More detailed control is left to Regulations which must be presented to Parliament, but I have good reason to remember that this apparent safeguard was of little use in the similar situation which arose when the National Health Insurance Bill was being discussed. Literally hundreds of regulations and amendments were rushed through a House which hardly even pretended to examine them, for it was not physically possible to do so. The situation in this respect is not likely to be more favourable in the hands of a Government which prides itself "on getting things done." If I am right in my belief that the provisions of this Bill indicate that the medical profession is in future to be under what amounts to a dictatorship, what is to prevent other professions and trades being similarly dealt with?

I call it a dictatorship because the reading of the Bill convinces me that the Minister, unless this Bill is radically altered, can, in future, do anything he likes with the doctors (and through them with their patients) except leave them alone. Did the electorate really think that this is what we fought for?—I am, etc.,

ALFRED COX.

PS.—The above letter was submitted to the *Times*, whose Editor regretted that he was unable to use it.—A.C.

SIR.—All are agreed that the best possible health services should be available to all members of the community, and the fundamental problem is to decide the best method by which this goal can be reached. The imperfections of the present system depend upon financial stringency, for the working classes have always been reluctant to reserve funds for emergency ill-health, and since the First World War the voluntary hospitals have been unable to supply sufficient beds and services to meet the needs of the country. Moreover, patients of the working classes cannot now obtain hospital treatment free of charge, as was the case before the First World War, and many resent having to pay even for part of these services. Another complaint has been that the rich can obtain better treatment than the poor, and it is believed that if doctors become whole-time salaried servants of the State they will be unable to discriminate between the different social classes. It is excellent political propaganda to nationalize the health services, for it is clear that some form of State aid is necessary on financial grounds, the money coming ultimately from the pockets of the working classes. The question is not whether a State service should be opposed, but whether the proposals are the best possible. Fundamentally, the conflict between the Government and the profession will depend upon the extent to which bureaucracy intrudes into the administration of an expert service.

The new Health Service Bill has a better administrative framework than that of the Coalition White Paper. I think it would have been better to place the teaching hospitals and medical schools under a department of medical education and research at the Ministry, for I am not convinced that the universities

always display a lively interest in late pre-clinical and clinical subjects. There must be a close association between the universities and the medical schools, but medical education and research are of such vital importance to the future of the Empire that they are worthy of special consideration, even to the extent of overriding the interests of the universities.

The pooling of the resources of the voluntary hospitals will cause great concern, and is probably based upon the Socialist idea of eliminating all "taint" of charity from the service. The Central Health Services Council is retained and will buffer complaints from all interested bodies. But who will be the mystical figures in the cloud-capped towers at the Ministry who have executive control? I cannot believe that the administration will succeed unless they are acknowledged experts in their particular branch. Apart from prophylaxis, what matters most in medicine are diagnosis and treatment, and I find it difficult to believe that a civil servant without medical training is the best person to have executive control.

For great achievement three essentials are required: (1) Experts at the top with executive control. (2) The best possible equipment. (3) A spirit of service and vigour among the executives. This rule holds in all walks of life, from the battles of Trafalgar, of Britain, and of El Alamein to any successful play or business. I am sceptical about No. 1 for the proposed health service. No. 2 has possibilities, and now we come to No. 3. I doubt whether a whole-time salaried medical officer will be content unless he has good working conditions, a reasonable salary, and hours of work corresponding to those of other salaried officials. In time he may ask for a forty-hour week as others do. He should have something more—what the Russians accept as "greater reward for greater service."

Whether the service will succeed or fail depends upon the members of our profession. If they join the service they must know what their commitments will be and for what reasons they can be dismissed, fined, suspended, or reprimanded. I think that doctors should have the power to refuse particular individuals as patients, for we all know how difficult some people can be. Many people will want to get something to show for their weekly contributions, which are substantial, and much more will be expected of practitioners and consultants than in the past; it may be impossible to contend with this extra pressure of work. At the moment, with the meagre information available, it seems to me that the profession cannot commit themselves to the service.

If we are allowed at any future date to negotiate with the Minister the responsibility of the profession in the service should be defined. It would be a great mistake in strategy if we allowed ourselves to be blamed for any failings of the service for which we were not responsible.—I am, etc.,

London, W.1.

WILFRED SHAW.

SIR.—In addition to the National Health Service Bill (Bill 94) the Ministry of Health has also published a "Summary of the Proposed New Service" (Cmd. 6761). The latter document is misleading in many points. For those who will prefer the summary to the Bill—the majority by reason of the greater intelligibility of the summary and the doctors from pressure of clinical engagements—a word of warning is necessary. Some of these points are:

1. Summary, Sec. 20. "... the Minister is to consult... bodies representative of..." The Bill, 1st Schedule, commits the Minister to consultation only with "... such organizations as he may recognize as representative..."

2. Summary, Sec. 24. There is no hint in the Bill of the intention that "Regional Boards, with their local Management Committees, shall enjoy a high degree of independence and autonomy within their own fields." Since it is not in the Bill the Minister cannot be held to the fulfilment of this "object."

3. Summary, Sec. 33. "Before making regulations he [the Minister] will consult..." This is nowhere mentioned in the Bill.

4. Summary, Sec. 41: "Professional" members of the [Executive] Council. These members are not "appointed by the local doctors, dentists, and chemists through their own representative committees," but are appointed by a committee which the Minister "may recognize" where he is "satisfied" that such committee "is representative" (Bill, Sec. 32 (1), and

thoracic XII, ilio-hypogastric, and ilio-inguinal nerves on four unpreserved subjects within 24 hours of death. In every instance the nerves had a different pattern and position, even on the two sides of the same subject.

From these observations and from practical experience I conclude that to be certain of blocking the ilio-hypogastric and ilio-inguinal nerves it is necessary to infiltrate the internal oblique muscle from 3 to 4 cm. cephalad to 2 cm. caudad to the anterior superior iliac spine in a line 2 cm. medial to the spine, and that the infiltration must be continued laterally and cephalad through the internal oblique and transversalis muscle to a distance of 3 to 4 cm. from 3 to 4 cm. cephalad to 2 to 3 cm. caudad to the iliac crest. Such an infiltration requires 20 c.cm. 1 in 200 novocain (procaine), 1 in 2000 nupercaine, or 1 in 3000 amethocaine in 0.9% saline solution.

When the correct technique has been acquired the results will be found satisfactory. Speed comes with practice.—I am, etc.,

F. R. W. KINKEAD ALLEN.

A Coincidence?

SIR.—The following two cases should be of interest, as I can find no reference in the literature to a relationship between history of twins and dextrocardia, and these two cases suggest a genetic relationship between the two. The cases were seen within two weeks of each other and were in no way related.

Case 1.—Male aged 44. On examination the apex beat was situated on the right side of the chest in the fifth interspace, $3\frac{1}{2}$ in. from the mid-line. The lungs appeared normal and liver dullness was on the left side. Clinical diagnosis of dextrocardia with reversal of viscera was made and confirmed by x-ray examination of the chest and barium meal. The patient gave a history that his mother and father were each one of twins.

Case 2.—Female, aged 48, with practically similar findings also confirmed by x-ray examination and barium meal. She gave a history that: (1) grandmother and grandfather were each one of twins; (2) sister had twins; (3) uncle had three sets of twins.

These two cases were seen during routine examinations in general practice, and on account of the rarity of the condition the possibility of further cases is remote. It is interesting to note that the man had been left-handed from birth, while the woman was normal in this respect. The relationship here between dextrocardia and twins may be purely coincidental, but it is possible that some genetic factor may be involved.—I am, etc.,

Leamington Spa.

JOSEPH C. JOYCE.

Bitterness

SIR.—I strongly suspect that the "bitterness" felt between Service and non-Service medical men is by no means one-sided. It will take all the calm reasoning of many Major Stallards to eliminate the feeling which undoubtedly exists on the side of the E.M.S. It is for us, therefore, to be tolerant and sympathetic to the resentment of those who did not go to war. The man who wanted to go and for one reason or another was not allowed to do so feels envious of his more fortunate colleagues, while the man who "dodged the column" cannot easily forgive those who come back after years of precious experience of mankind and stirring events, with the horizon of their minds widened in a way that should fortify them against any and every adversity that they may encounter in the future.

To the disgruntled Service man I would say: "Knowing what has happened (and your father would have told you exactly the same story after the last war) and if you were put back to 1939 would you have done any differently? Of course you wouldn't; because you are you and not the man next door. Well, then, don't grumble about it. Just be sorry for the man who has been deprived of these rich experiences, either by misfortune or by the narrow ambitions of his own mind."

Dr J. M. G. Wilson (Oct. 6, p. 477) seems to be suffering from a rather pathetic inferiority complex. Any man who is not the better for his life in one of the Services must have been blind to the world in which he moved. The worst if not the only defect that one notices at the end of a Service doctor's career is a slightly reduced capacity to suffer fools gladly. No doubt even this cardinal virtue will be restored to him after

a month or two of the less pressing conditions and more evolved self-discipline imposed by civilian life.

I must protest also against what Squad. Ldr. J. L. Brown has to say about "time-wasting sanitation." Most of my time has been spent in doing surgery in the forward areas of North Africa and Italy, but for three months I had to battle with the problem of keeping a meagre force of French *maquis* "in the field" (literally) and free from epidemics. This force was totally untrained in the elements of hygiene, and as short of paper as it was of soap and even water. The inculcation of a few ideas on "time-wasting sanitation" served a more useful purpose in the war effort than the exhibition of technical surgical skill on a few individuals. Moreover the emphasis in medical practice of the future is more and more in this direction.—I am, etc.,

GEOFFREY E. PARKER,
Major, R.A.M.C.

Millbank S.W.

An Institute of Medical Photography

SIR.—Almost twenty years of hospital clinical portrait photography of the highest quality and usefulness, carried out by my colleague Dr A. H. Turton in the skin department of the Royal Victoria and West Hants Hospital, has taught us several lessons that the patient should be photographed promptly, when first seen, before treatment has altered appearances; that this should be done by the practitioner himself who can reach the patient wherever he is, or by the member of the hospital staff who picks out patient and posture, rather than by any layman. Delay in taking the photograph only means that likely cases will slip away, or will not be seen again in the same interesting phase of the illness. It seems unlikely that a hospital authority would interest itself, whether in the matter of money or photographer or dark-room accommodation, in what is purely a professional concern, a diagnostic refinement, well-intentioned though it might be.

Mr. H. Mandiwall suggests (Oct. 6, p. 479) that the first thing needed is a competent photographer, and he is right: this is the crux of the whole matter. The clinical photographer must be self-trained; no snapshot is good or near enough; a suitable camera with portrait lens is a necessity, and a good light with screening for background desirable. To go along with each negative and print there must be a full caption; without this the value of the picture is vastly lessened.

In time coloured photography may come into vogue; but in skin patients particularly the coloured portrait of a well-executed tinted wax cast, though taking much art and time in production, can present a life-like image. Coloured prints of static moments, or kinetograph reproductions of movements in disease, require specialized knowledge and apparatus, and cost much in time and money; in any case they have a limited use only. For demonstration purposes, though colourless, the ordinary well-taken photograph and the lantern slide prepared from the negative are of the most use to the practitioner, and the photomicrograph to the pathologist; but only if captioned amply enough.

The best service to be rendered by an institute would be as a centre for London meetings and demonstrations in clinical photography, for storage of pooled negatives and prints that over-fill shelves and cupboards; but, most important of all, to issue a monthly or quarterly photographic journal to serve a similar purpose in medical journalism as the illustrated daily does in the newspaper world; run on business lines and for members of the profession and medical libraries, exclusively. Such a journal published under the aegis of the British Medical Association—to control policy, printing, and separate sale—would serve the purpose admirably.

In the past the pictorial art has been made too little use of in medical literature and practice; nor has the profession been well served in the matter by its journals. "The pictures for the page alone"; not to take and print a good photograph is to cast a pearl away. There is a saying which has truth in it: "Better a picture than a thousand words." A photograph is the next best thing to contemplating the patient in person; besides, seeing is believing, and might spare one a little the laborious reading of wordy books and papers.—I am, etc.,

Bournemouth.

S. WATSON SMITH

"Reasons" for Scientific Research

SIR.—I was delighted to read the leading article on Pasteur *apt.* 29, p. 429), but two remarks need further elucidation on ascribe the famous retort, "What is the use of a newborn baby?" to Benjamin Franklin. I have always understood it have been uttered by Faraday when asked to the use his discovery of the relation between electricity and magnetism.

Your remark that there are "present-day scientists who would restrict scientific research to subjects of 'social value'" is also need of some explaining. Who are these scientists and what meant by "social value"? Surely all research is of value human society, with the exception of certain researches conducted at Belsen and Buchenwald. When one discusses the value of research it is important to remember that research justifies many values and needs and that it is conducted for many purposes and reasons. I know of only two theories on the reasons for scientific research. One theory states that it is done solely to satisfy the curiosity of research workers and presumably those who finance them. The other states that research is of two kinds: practical and theoretical. The former applied to problems arising out of the current practice of society; the latter kind of research is applied to the theoretical problems arising out of the practical problems and out of previous theoretical problems. Since the latter theory explains only "why" research is done but also "what" research is one, it should be possible to decide between these theories by practical investigation. After all, human curiosity being innate, always the same.

I would be delighted to hear an explanation of the fact that we can spend £5,000,000,000 on the atomic bomb, while there is not even £1,000,000 a year for medical research—in terms of human curiosity and a disinterested passion for truth.—I am, etc.,

M. HAMILTON, Fl. Lieut.

Press Publicity

SIR.—It is rather a fortunate coincidence that concurrent with the letters from Sir Adolphe Abrahams and Mr. John Langdon-Davies on press publicity (*Sept.* 29, p. 444) appears a suggestion in the *World's Press News* by Mr. W. E. Dick, the editor of *Discovery*, that there should be formed a Guild of Science Writers. He suggests that membership of the guild would require the writer to hold some scientific qualification, a token on both the newspaper and the scientific worlds of the individual writer's competence to handle scientific subjects.

As a writer for many years on medical subjects I welcome both the suggestion of Mr. Dick and the letters of Sir Adolphe Abrahams and Mr. Langdon-Davies, especially the knowledgeable remarks of the latter. The trouble is that the average journalist is practically entirely ignorant of medical knowledge; indeed he often knows less than the young first-aider. He knows nothing of medical history; Harvey to him is probably a boxing exponent; he cannot distinguish between the sulphonamides and sulphanilamide and lumps them all under M & B. The result is that when he has to cover a medical story he cannot meet the doctor or surgeon on his own ground or talk the same language, and so chooses the sensational angle from scraps that he can understand to hide his lack of knowledge. Obviously the cure for this is not the responsibility of the medical profession; it is for editors and newspaper proprietors to see that a medical or scientific journalist is on their staff or at call to cover such stories.

Mr. Langdon-Davies's remark about the voluntary hospitals and publicity is much to the point. Where voluntary hospitals issue news items it is usually done by an appeals secretary, who is very seldom a trained journalist, with the result that many a genuine story of wide appeal is overlooked or badly handled—the loss being that of the hospital concerned and the voluntary system. The solution here is for every voluntary hospital to have a journalist as its press officer, not necessarily in a paid capacity, though any hospital that paid a good journalist a small retaining fee would repay itself many times over in the course of a year.—I am, etc.,

NORMAN K. HARRISON.

Humanitarianism and the European Situation

SIR.—I have read with interest the letter from Lieut.-Col. Eric Townsend (*Sept.* 29, p. 446) regarding the present position in Europe, and I think that his suggestion about the care of European children is an excellent one, and one in which I, for my part, would be glad to assist, both as regards taking such a child and in any other way possible—I am, etc.,

D. F. MCCARTHY,
County Medical Officer of Health.

SIR.—May I thank Lieut. Col. Townsend for writing, and you for publishing, his letter? I hope it will be the means of stimulating into action many who share his concern. It has had that effect on me, and I write to say that I will gladly take two children under the age of, say 10, as he suggests, for the period of one year, and I should prefer two German or Austrian children. I will also gladly take part in any committee or administrative work that might be necessary to give practical effect to the scheme.

I appreciate the difficulties in the way and quite see in advance arguments which may be used about the shortage of transport, the dangers from a psychological point of view of taking children away from their parents, etc. I would only suggest that there are unfortunately numberless children who have already lost their parents and their homes in Germany and elsewhere, and that it is to these children and others that we must look to safeguard the future peace of the world. Apart from the opportunity of saving them from the threat of death this coming winter, there would be the constructive opportunity of ensuring that they will be able to make the best possible contribution in the future.

As to transport, when it was a question of saving our own folk from Dunkirk we laughed at difficulties and they ceased to exist. We have only to care equally in this present desperate situation for the equivalent of the little ships and the individual homes to overcome the difficulties once more. Since Col. Townsend said that he was leaving for the Continent and had to leave the follow-up of his idea to someone else, so great is my own concern that if no one else takes the matter up may I ask that any others of your readers who are prepared to help should get into touch with me?—I am, etc.,

12 York Road, Harnage

KATHLEEN RUTHERFORD

Alien Doctors

SIR.—There is little doubt that most of your readers have been distressed by the recent letters vilifying alien doctors. It is, I hope, not griggishness that prompts me to put in a word on the other side. Certainly it seems only fair play that this should occasionally be done. Further, repetition in print does have an effect on the reader, and the effect in this case is one that promises release of nastiness.

If we are a profession of gentlemen (otherwise we are surely not a profession) then we are ashamed of these lapses into bad manners. If we still have any British courage then we fear no competition, and even look forward to a test that may be as stimulating as it should be valuable to us and the community. If we are a nation of calculating shopkeepers then we recall the profit to British medicine from the work done here by those with foreign names.

It was Rome's proud boast to be a city where no man is an alien save the barbarian and the slave. Some 800 years before Sidonius made this claim, Hippocrates said the physician "must be a gentleman in character, and being this he must be grave and kind to all."—I am, etc.,

A. C. LENDRUM.

SIR.—Capt. John Nesfield (*Oct.* 6, p. 478), is afraid he will be out of a job when he gets back. The natural reaction is to find an outlet for this, and the most convenient scapegoat is the Jew, the favourite one in all countries, unfortunately, and in all ages (What a wonderful role the Jews have, and why is this correspondence about alien doctors when what is meant is Jewish refugees, as most of them are Jewish?) This fear exists in spite of there being an acute shortage of doctors here, and even if all were released there would still not be enough

to man the new health scheme. As to numbers, Capt. Nesfield knows as much as I do, which isn't much. But I still believe in the kindness of the average Briton. If the numbers prove to be small (and there is at least as much reason to suppose this as to accept the wildly exaggerated statements of Capt. Nesfield), then I hope that Christian conscience and innate British decency will allow them to remain. And in spite of the fact that Irishmen volunteered during the war it still remains true that Eire was neutral throughout and that Jews as a people lost more proportionately than anyone else in the war, not excluding Russia.—I am, etc.,

Loxwood, Sussex.

J. VINE.

SIR,—In spite of the many letters which have appeared in the *Journal* during the past year or so on the subject of alien doctors, I have failed to find a single remark with regard to the attitude of the British public towards these foreigners. Surely the people whose health has been entrusted to the alien doctors should have a say in the matter. The fact, as stated by Capt. Nesfield, that a very large number of them "are entrenched in and around Harley Street" seems to prove that they are more liked by their British patients than by their British colleagues, or shall I say they are disliked by their colleagues for this very reason?

I wonder whether Capt. Nesfield has taken the trouble to find out for himself the exact number of alien doctors serving in the Forces to call it disproportionate. I am one of those who volunteered early in the war and was enlisted in the Pioneer Corps. Building Nissen huts, guarding petrol dumps, and the like was our service until, in 1941, we were given an opportunity of medical employment as civilians and released from the Army. If the Government had wanted to use us as medical officers they could have directed us accordingly. Let us be quite frank. Is the "great anxiety felt by members of the profession over-seas about our presence in the U.K." solely due to our professional inefficiency, and is the demand for us to leave this country essential for the well-being of the population which we tried to serve best during the war? If not, what then is the reason for the great anxiety?

I am quite aware, together with some of the "strange importations" as we were once referred to, that we shall be made superfluous when most of the British Service doctors will have been released. But I should have expected at least a more academic approach to the problem by some of our British colleagues, even though we are only temporary members of this noble profession.—I am, etc.,

Macclesfield.

M. TANNENBAUM, M.D.Graz.

SIR,—Capt. Nesfield has complained of alien doctors "entrenched in and around Harley Street and all over London." He says that of these a disproportionately small number have attuned in the Services during the war. Capt. Nesfield overlooks the fact that only a small number of these doctors could have joined up, as only a small number of the applications for naturalization had been granted. The naturalized doctors who were fit and of military age have joined the Services. Capt. Nesfield wants the alien doctors to be turned out. I wonder if he has ever spent a thought on the question as to where they would go. He will know that most of them are of Jewish extraction and that their parents, relatives, or friends have been slaughtered in Germany. How can they live or practise here? Palestine, the land promised to them by the Balfour Declaration as a National Home, is now more closely and jealously guarded than ever against their entry.

After obtaining a British qualification these doctors have built up their practice, facing difficulties and handicaps quite unknown to their British colleagues. A large percentage of their patients are refugees, who have been attended by them before they were driven out by the Nazis. The rights of those who have fought for this country must be recognized. These rights are not endangered by the presence of a few alien doctors in the Harley Street district. These Jewish doctors are not "entrenched" here like a hostile battalion, but long to become British and to work together with their British colleagues.—I am, etc.,

Fulham, W.S.

H. LYTTON.

Nutritional Macrocytic Anaemia

SIR,—In the leading article in which the pathogenesis of nutritional macrocytic anaemia is discussed (Oct. 13, p. 501), you refer to the work of Moore and his colleagues showing that the macrocytic anaemia of pellagrins is apparently due to lack of an extrinsic factor normally supplied by dietary protein. It may therefore be of interest to your readers to know that recently we have found that rats on a diet of methionine develop a macrocytic anaemia characterized by changes in the peripheral blood and in the bone marrow similar to those in human nutritional macrocytic anaemia (Glynn, Himsworth, and Neuberger, *Brit. J. exp. Path.*; in press). The development of this anaemia is not prevented by large supplements of cystine or of iron.—We are, etc.,

Obituary

R. CUNYNGHAM BROWN, C.B.E., M.D.

We regret to announce that Dr. R. Cunyngnam Brown, late Commissioner of the Board of Control for England and Wales, died on Oct. 7 in retirement at Lymington, Hants.

Robert Cunyngnam Brown was born in 1867, second son of the Rev. Robert Brown, of Paisley. He was educated at the Universities of Glasgow, Durham, and Frankfurt, graduating M.B., B.S. of Durham in 1890, and M.D. in 1898. After holding several resident hospital posts and three years in general practice, he worked under Carl Weigert in his neuropathological laboratory at Frankfurt a.M. This was followed by a year and a half at the National Hospital for the Paralysed and Epileptic, London, and a period as pathologist to the County Asylum, Chester. In 1899 Cunyngnam Brown entered the Prison Service as deputy medical officer, and twelve years later was transferred to Scotland as Deputy Commissioner in Lunacy. In 1915 he was seconded to the R.A.M.C. with the temporary rank of major, and held the post of officer-in-charge of Strongburn-Woodside Military Hospital, Glasgow; he then went over-seas for service in Macedonia with the 37th British Hospital attached to the Serbian Army and as mental specialist to the Salonika Command. He was recalled to England and lent to the Ministry of National Service, and in 1919 was officially transferred to the Ministry of Pensions as Deputy Director-General of Medical Services, retiring in 1925. For the next six years he was a Commissioner at the Board of Control. His services in the war of 1914-18 were recognized by decorations from the Portuguese and Serbian Governments, and he was mentioned in dispatches.

Cunyngnam Brown was an able and fluent writer, and everything he wrote or said or did bore the mark of enthusiasm and good will. He was joint author of a paper on diffuse encephalitis in *Brain* in 1892, wrote two clinical papers for the *Lancet*, and an article on the boarding-out of the insane in private dwellings for the *Journal of Mental Science*; he also prepared a report on the family care of the insane poor for the Royal Commission on the Care and Control of the Feeble-minded. He was a valued contributor to these columns for some years, and his occasional visits to the editorial office made one feel that a breath of genial sea air had come to London.

DR. ALFRED COX writes:

Cunyngnam Brown has been a friend of mine for nearly 60 years, though we met rarely. He was fellow student of mine at Newcastle-upon-Tyne and one of the most popular men in college. He had many advantages—he was a son of the manse, he had a good brain, a handsome and imposing presence, and a sweetness and generosity of disposition which characterized him all his life. In spite of the important official positions he held, always with credit and distinction, Brown was never much in the limelight. He went about the world a good deal on official missions and generally turned up at B.M.A. headquarters to report himself to me and the Editor. He was a favourite with everybody who knew him, and he had the happy family life he deserved until two of his sons failed to get away from Malaya when the Japs invaded it. I had heard nothing

of him since I was told that he and his wife were going East to look for them. I hope he was successful. His heart was as big as his body, and that is saving truth.

K. W. M. writes:

Robert Cunningham Brown numbered Dr. John Brown of *Rob and his Friends* among his forebears, and on his mother's side was a Highlander. After a medical course in the Universities of Durham and Glasgow he went to Frankfurt to study neurology, and on returning to Great Britain was appointed a clinical assistant at the Queen's Square Hospital, where he made a special study of tabes dorsalis. He went then into the Prison Medical Service, and in more than one institution was responsible for improvements in the treatment of inmates, more particularly in the provision of reasonable occupation and opportunities for education. His work in this respect left its mark on the whole prison service. He left HM Prison, Birmingham, in 1912 to become Deputy Commissioner of Lunacy for Scotland.

On the outbreak of war in 1914 he applied for military service, and was put in charge of Woodside and Sprinburn Military Hospitals, Glasgow. Thence he went in May, 1916, as captain, R.A.M.C., to Macedonia with the 37th General Hospital attached to the 1st Serbian Army; and after acting later as consultant in mental disease to the Salonika Command was recalled in 1918 to join the staff of the Ministry of National Service. He was transferred in this year to the Ministry of Pensions, where he filled the office of Deputy Director-General of Medical Services. His experience as a civil servant stood him in good stead in this important post, and it was due to his advice on policy that the system of Pensions Boards and other complicated machinery for dealing fairly with the returned soldier were set up. Ill-health traceable to severe dysentery in Macedonia compelled his retirement from the Ministry of Pensions in 1925, but he surprised his friends by a complete recovery, and was appointed a Commissioner on the Board of Control for England and Wales in 1927. He served in this office until his final retirement in 1933.

During the earlier part of his professional career he published several papers of recognized importance on neurological subjects; later he did much reviewing and article-writing for medical journals, particularly for the *British Medical Journal*, with whose late Editor, Sir Dawson Williams, he enjoyed a close friendship. In the various services to which he was attached—the Prison Medical Service, the Ministry of Pensions, and on the Board of Control—his influence was great and abiding, owing first to a far-reaching intelligence which enabled him to see the implications of problems, and particularly their implications for persons—for the prisoner, the pensioner, and the mentally afflicted—but above all to the complete integrity of his character. As to the latter, it is difficult to speak plainly. The more intimate his friends, the more they came to grasp his complete selflessness in every relationship into which he was brought by his work and by the other occupations of every day. He was repaid by the deep affection of many, the only coin which he valued, though it is certain that he never counted what was given him. During the last year he had to bear the affliction of almost total blindness from glaucoma, and a few days before his death he heard of that of his second son on the Bankok-Moulmein railway in 1943; but almost at the same time he also heard of the safety of his third son in Singapore, whose fate had been unknown since February, 1942. His wife, a daughter, and his third son survive him. A distinguished public servant, a great doctor, and a splendid friend.

A. S. writes:

The words "a great gentleman" are not lightly to be used, but none who knew "C. B." would question his possession of all that they imply. Tall, handsome, debonair, his physical presence impressed, whilst his voice and greeting showed an immediate personal interest, whoever you might be. This initial charm did not fade as one came to know him better; it was a true expression of the man. He could indeed be sharp and peremptory if need be, he could be unreasonable or inconsequential, but he was never small-minded or self-seeking. He believed the best of his fellow-men, and evoked the best from them.

As Deputy to the Director-General of Medical Services of the Ministry of Pensions, Sir Lisle Webb (whose death has strangely occurred on the same day), he was a loyal, strong support through the difficulties of the early post-war years, and his wide experience of mental and allied diseases was invaluable in solving many clinical and administrative problems. By his colleagues, medical and lay, he was beloved. An endearing trait was an absent-mindedness which lost him countless umbrellas, and once, it is said, while visiting an office at Northampton he suddenly remembered it was Southampton to which he had set out.

For health reasons, fortunately temporary, he retired from the Ministry after only six years' service; but, though the loss was great, his influence remained. During the late war he returned as a specialist on medical boards; as keen, as energetic, as courteous as ever, bearing heavy domestic anxieties and sorrows with a smiling fortitude.

JOHN WOOD, M.B., Ch.B., D.T.M.

The sudden, unexpected death of Dr. John Wood of Bournemouth has brought much sorrow to all who knew him as physician and friend. Born in Aberdeen in 1890, he was educated at Gordon's College there, afterwards at the University, where in 1912 he graduated in medicine. From the first his intention had been to educate himself for work in the foreign mission field. With this end in view, immediately on qualifying he became house-surgeon at the Worcester Royal Infirmary; later he proceeded to take the D.T.M. at Liverpool (1915) in preparation for medical missionary work under the aegis of the Church of Scotland. After ordination he was directed to Calabar, Southern Nigeria, West Africa, for duty and in charge of the Mary Slessor Hospital at Zitu on the Cross River and of eleven widely-scattered mission stations based on the hospital. After some time there he was transferred to a newly built hospital and mission station at Uburu, where he continued to do valuable pioneer work. Being young, keen, active, and conscientious, John Wood speedily mastered the local dialects and made his work indispensable; he was held in high esteem by the natives among whom he ministered. In the end his health and his wife's health suffered so severely by reason of the death-dealing environment in which they lived and worked, and by the poor sustenance that the country afforded, that both were ordered home for good.

John Wood, on his return, settled in practice at Wigan, being appointed assistant surgeon to Wigan Royal Infirmary and medical officer and vaccinator to Wigan Union. After five strenuous years, for health reasons, he relinquished practice there and settled in Gournemouth, where he continued to live and work for his remaining years, by his gentleness, his sympathetic kindness, and his conscientiousness endearing himself to all who came into contact with him. It was the divine side in John Wood that brought him of his own free will to sacrifice himself for others by accepting missionary work, and in the parasite-infested wilds of West Africa. In all he did he seemed to be guided by an abiding faith to support in him a matchless fortitude and determination in a nature both kind and gentle. Constantly, in all manner of ways, he strove to do good and to help and encourage others, with never a thought of self. There were in him all the fine qualities of the stock from which he came: all the virtues went to build in him that nobility of character we knew to be his. Near the surface, often breaking out unexpectedly, lay a pawk, dry humour that was characteristic of Scottish. He possessed the quiet, tranquil mind along with a becoming humility, owning all the attractive attributes with which Nature endowed the true gentleman. Of all men, John Wood could claim to say, "I have fought the good fight, I have finished the course, I have kept the faith." Much sympathy will be felt for a man and five children in their grievous loss. S. W. S.

We regret to announce that DR. ROBERT EDWARD BURNETT formerly of Moreton-in-Marsh, Gloucestershire, died in hospital at Chichester on Sept. 25. Born at Moreton on May 12, 1866, the son of a medical man, he was educated at Chipping Campden Grammar School and the University of Edinburgh, where he graduated M.B., Ch.B., in 1888. Dr. Yelf was for many years surgeon to the Moreton Cottage Hospital and district M.O. for the Shipston-on-Stour Union, and M.O.H. for Stow-on-the-Wold Rural District Council. During part of the war of 1914-18 he served as temporary lieutenant, R.A.M.C. He joined the B.M.A. immediately after graduation, was chairman of the Oxford Division and president of the Oxford and Reading Branch in 1908, and was made an Associate Member of the Oxford Division in 1931 when he left Moreton-in-Marsh to live at Selsey. In Moreton and for a wide radius around he had identified himself with every aspect of local life. On his departure a presentation, subscribed to by 730 people, was made to Dr. and Mrs. Yelf to mark the affection and esteem in which they were held. His father, whom he joined in practice in 1888 and succeeded in 1895, was one of the founders of the cottage hospital. In his younger days Dr. R. E. B. Yelf was a keen sportsman and captain of the local cricket and football teams. He had been for many years honorary secretary of the Moreton Working men's club, chairman of the parish council, and at one time captain of the fire brigade. After leaving the Cotswolds for Selsey he became an active member of the bowling and tennis club, and did much to maintain the greens and courts when the regular staff were away. During the war, though retired from active practice, Dr. Yelf took on a great deal of medical work once more in order to replace the younger medical men who had joined the Forces, and up to the time of the short illness which preceded his death he was working in the village among his numerous patients, with a cheery smile and a word for everyone he passed on the road.

The Services

Surg. Capt. F. L. Cassidi, V.D., R.N.V.R., has been appointed an Honorary Surgeon to the King.

Surg. Cmdrs. E. C. Johnson, A. L. Gunn, and G. P. McCullagh have been awarded the R.N.V.R. Officers' Decoration.

Acting Group Capt. Sir Louis L. Greig, K.B.E., C.V.O., R.A.F., has been appointed an Officer of the Legion of Merit by the President of the U.S.A.

Acting Surg. Lieut.-Cmdr. J. S. Guest, R.A.N.R., has been appointed O.B.E. (Military Division) for great skill and devotion to duty as Principal Medical Officer of H.M.A.S. *Westralia* during the landing on Tarakan Island on May 1.

Surg. Lieut.-Cmdr. W. H. Milroy, R.A.N.R., has been mentioned in dispatches for skilful organization and for courage and devotion to duty in the operations covering the assault landing of 2/48th Assault Battalion, 9th Australian Division, at Tarakan on May 1, while serving in one of H.M. Australian ships.

The following appointments, awards, and mentions in dispatches have been announced in recognition of gallant and distinguished services in the field:

M.B.E. (Military Division).—Lieut.-Col. (Acting) W. E. A. Buchanan, T.D., Lieut.-Col. (Temp.) J. C. Mackay, M.C., T.D., Major W. L. Kinnear, and Major (Acting) J. D. Finlayson, R.A.M.C. M.C.—Capt. J. Burns and Lieuts. R. Mackay, D. J. Macrae, F. W. M. Plant, and G. E. Stoker, R.A.M.C.

Mentioned in Dispatches.—Major (Temp.) C. H. Imrie, Capt. J. Morrissey (killed in action), Capt. (Temp.) A. Taylor-Smith, and Lieut. G. H. Darke, R.A.M.C.

Freed in the Far East.—Lieut.-Cols. H. C. Benson and C. W. Maisey, Major P. B. Hanbury, Capts. A. Barber, G. Blair, A. W. Frankland, D. W. F. Gotla, and V. W. J. Hetreed, R.A.M.C.; Major S. C. Colbeck, I.M.S.; Surg. Lieut. D. R. Syred, R.N.V.R.; Fl. Lieut. R. F. Braithwaite, R.A.F.V.R.

Repatriated.—Col. Julian Taylor, A.M.S.

CASUALTIES IN THE MEDICAL SERVICES

Killed.—Capt. Jacob Hyman Joseph, R.A.M.C.

Died.—Major Campbell William Kidson and War Subs. Capt. Denis John Burgess, R.A.M.C.

Died at sea while on active service.—Major Vivian Roy Clifton, R.A.M.C.

Wounded.—War Subs. Capts. J. G. A. Gilruth and J. A. Perpoli, M.C., and Temp. Lieut.-Col. J. M. Scott, R.A.M.C.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The *Cambridge University Reporter* dated Oct. 9 contains a copy of the letter from the Home Office informing the Vice-Chancellor that the King by Letters Patent under the Great Seal bearing date Sept. 1 appointed Sir Lionel E. H. Whitby, C.V.O., M.D., F.R.C.P., to be Regius Professor of Physic in the University. The *Reporter* also prints the full text of the address to the Senate given in Congregation on Oct. 1 by Dr T. S. Hele, Master of Emmanuel College, on resigning the office of Vice-Chancellor. Speaking of medical events the past year Dr Hele recalled that through the kind offices of the Medical Research Council a Chair of Experimental Medicine had been established for Dr R. A. McCance, whose department is receiving further assistance from the same source. Addenbrooke's Hospital and the University were collaborating closely in the development of the School of Clinical Research. In the Shire Hall under Dr Robert Ellis, chairman of the Cambridgeshire County Council, the future of the medical services of the area had been discussed by representatives of local authorities and hospitals, with representatives of the University present on these occasions. For the next five years the difficulties arising out of the enforced use of temporary and inadequate accommodation for the hospital services of the area would delay the full development of the School and of the ancillary services which the University would help to provide for the maintenance of health and for the diagnosis and treatment of disease. "Our guests—should I say paying guests?—from other Universities with one exception have departed, taking with them our very best wishes for the re-establishment of their work at home, and with grateful acknowledgment of the mutual help and inspiration which their presence in Cambridge during six critical years has engendered. St Bartholomew's Hospital Medical School will return to their premises in Charterhouse Square when sufficient repairs have been completed."

Titles of the degrees of M.B., B.Chir. were conferred by diploma during the months of July, August, and September, 1945, on J. S. Keillin and C. N. Smith, of Girton College, and on I. M. S. Chappel, P. J. Coope, M. E. P. Hele, L. A. Norris, H. M. Russell, J. Whitham, and G. B. Wrong, of Newnham College.

Names of candidates for the M.Chir. examination should be sent to the Registry by Jan. 1, 1946; the examination begins on Feb. 19.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At a meeting of the Council, held on Oct. 6 in the College House, with the President, Mr. Eardley Holland, in the chair, the following were admitted to the Membership: T. S. M. Barnett, A. Buchan, Daphne W. C. Chun, Aileen M. Dickens, E. D. Y. Grasby, M. W. Hemans, Ursula M. Lister, Agnes M. D. Milne, Abd El-S. M. El-Minabbawy, K. Mitra, Joan P. Moignard, P. Raj, W. B. Shute, Beatrice M. Smyth, J. M. Thomson.

Medical Notes in Parliament

Industrial Injuries Insurance

Mr. JAMES GRIFFITHS moved the Second Reading of the National Insurance (Industrial Injuries) Bill. He said that of the four measures needed to give effect to the White Paper scheme for a comprehensive system of social insurance two had passed into law. The first set up the Ministry of National Insurance. The second was the Family Allowances Act. This Bill was far more involved than either. The fourth would be even more complicated than the third, the present Bill. The broad principles on which the scheme of industrial injuries insurance was based had been outlined in the White Paper on Social Insurance. In accordance with this the Bill was to make compensation for industrial injuries a part of the country's social services and to make these injuries a matter for settlement on the basis of fixed benefits to be paid for a fixed premium. The Bill would be the end of "compounding." All persons employed in Great Britain under any contract of service or apprenticeship would be insurable without any income limit. Certain other people were being brought in—for example, members of lifeboat crews, employees of any local or public authority, taxi drivers, and members of rescue and fire parties in mines and works. Seamen and other persons employed for the purpose of the vessel or of the cargo or of passengers on British and British-owned ships, and civilian airmen employed on British aircraft were covered. Criticisms of the present Acts on the ground that the onus of proof always rested on the worker had been met by addition of a proviso that, for the purposes of this Act, an accident arising in the course of an insured person's employment should be deemed, in the absence of evidence to the contrary, also to have arisen out of that employment.

Expounding the details of the Bill, Mr. Griffiths said that, where at the end of an injury benefit period an injured man still suffered from disablement which was likely to be permanent or was substantial, he would be assessed for pension. This would be awarded in proportion to his loss of health, strength and power to enjoy life. It would be awarded irrespective of his earnings. The disabilities which were to be regarded as attracting a pension of 100% were to be prescribed later. If a pensioner had to enter hospital for further treatment or account of his injury he would, so long as he was in hospital, receive pension at the full 100% rate irrespective of his normal assessment, but subject to a reduction of 10s. a week in respect of home savings. To-day a man could not draw sickness benefit and workman's compensation for the same injury. The Government had decided to modify that. Under its scheme a pensioner who was unfit for work would be entitled to sickness benefit even when his unfitness was due to his injury, subject to the provision that, if his pension was at the 100% rate, sickness benefit would be at half rate until he had paid ten contributions since the date of his accident. All benefit rates were on an equality for both men and women. As this was a State system of insurance, claims would be decided by officers appointed by the Minister to be insurance officers. Independent local appeal tribunals would hear and decide appeals from the insurance officers' decisions. There would be a final appeal to a Commissioner who would be a legal expert appointed by the Crown. The Bill contained a provision for financial aid to be given to persons engaged on research into the causes and prevention of industrial accidents and disease and for the Minister himself to employ persons to carry out such research. There was also a provision enabling the Minister to provide artificial limbs and other appliances to pensioners either free or at

reduced rates. There was to be appointed an Industrial Injuries Advisory Council to which he would ask employers' and workers' organizations to nominate members. To the injured man the cash payments were not the most important thing. The most important thing was that he should be fitted for a new life. That was where the old system failed completely.

DEBATE ON THE BILL

Mr. OSBERT PEAKE said one of the great merits of the new scheme was that by a new method of assessing disability it provided a firm basis of supplementary schemes. There must be a close link with the new health and hospital services of the Ministry of Health and with the rehabilitating and retraining services of the Ministry of Labour. Miss BYRON hoped the equipment provided would include invalid chairs and spinal carriages. The cost of these was beyond the capacity of injured workmen to pay. Mr. CLEMENT DAVIES spoke of the conditions in the quarrying industry of North Wales in galleries where the candle would not remain alight when it was standing up. The men worked in such conditions of dust that they could not be seen by men within two yards of them. Yet that type of workman was outside the scope of the Workmen's Compensation Acts. He asked why the small employer who had only one employee was outside the scope of the Act. With a broader measure there would be no legal question but only a medical question, with the medical man saying that a person was fit or unfit and what assistance he would require to rehabilitate himself.

Mr. CLITHEROW said that he himself was a final-year medical student. He asked the Minister to insert words so that the Bill should include health workers who contracted tuberculosis through being directly in contact with tuberculous patients in the course of their normal duties, or within a reasonable time afterwards. He suggested this because of his own observations both as a medical student and as a member of the Liverpool City Council sitting on the Hospitals' Committee. Nurses and health workers and the medical profession themselves had a thorough medical examination before they started. At their first start they were far healthier than the average. He gave instances of medical students who had fallen ill with tuberculosis. His observations were that one in every fifty medical students went down with tuberculosis during the three years of clinical work. It was distressing to the Liverpool number of nurses whose names appeared before the Liverpool Corporation Hospitals' Committee as having gone down with colds, and eventually with tuberculosis. The committee paid them a full salary for about three months, half salary for a further three months, and then cast them off like an old glove. Counsel's opinion had been that tuberculosis was not an industrial disease. Even if a girl could prove that a patient with an active lesion coughed in her face, and that pulmonary tuberculosis could be attributed to it, that was deemed to be an accident. He hoped that in the Committee stage an amendment would be made to include these girls.

Dr. STEPHEN TAYLOR said the Bill got rid of the endless legal and medical wrangles which had wasted so much money, but it perpetuated the distinction between industrial injury and non-industrial injury and disease. He hoped the Minister would assure the House that all nurses would be covered in the Bill, particularly those working on private nursing. With every safeguard the nurse was liable to septic fingers, kidney infections, and septicæmia. Regular x-ray tests, Mantoux tests, and blood counts were not done. Admittedly, in good sanatoria the nurses were not more liable to tuberculosis than the rest of the community, but he was pretty sure that taking the nursing profession as a whole they were more liable. The ill of the nursing were not in the Schedule of Industrial Diseases. In the past, trade unions had to waste their energy getting diseases scheduled when that energy should have been used in getting rid of the diseases. Research workers spent their time proving a connexion between the disease and the occupation instead of trying to get rid of the disease. The Bill gave the Minister power to promote and assist research into the causes, incidence, and methods of prevention of industrial disease. He hoped that to this the Minister would add research into the treatment of industrial accidents and diseases, because this treatment was still far from perfect. Good work had been done in this field by the Industrial Health Research Board. He trusted the Minister would use the Board and the Medical Research Council, and would strike out on his own in the research field. He must provide his research workers generously with field workers, clerical staff, and laboratory technicians. Mental disability made up a large part of industrial disability. He hoped the Minister would also generously promote research into industrial psychiatry and on the measurement of fatigue, of accident-proneness and so on, and that he would encourage the work of those psychiatrists who had been busy in the Army. They should help the industrial neurotics over their stiles.

Mr. DAVID WILLIAMS spoke on silicosis and pneumoconiosis. This existed on a staggering scale in West Wales, where one colliery from Jan. 1 to Sept. 29, 1945, had lost 200 men—more than one in eight. Once a man was certified to be partially or totally disabled with these diseases he did not return to the mining industry, so that 20% disability in such cases caused greater hardship than 20% physical disability resulting from accident.

Dr. H. B. MORGAN said that in some workshops new organic solvents were being used upon which practically no research had been made. In some of the finest factories in Great Britain solvents were in use which the workman was forced to inhale, and which in three months would give him anæmia from which he would never recover. He asked whether it was true that in Wales and the North-West the number of cases awaiting decision by the Silicosis Boards were two years in arrears. Was it true that the Government was doing practically nothing to train doctors for those positions?

REPLY FOR THE GOVERNMENT

Mr. LINDGREN, replying for the Government, said the Minister desired that the provision of artificial limbs and surgical appliances should include wheeled chairs, spinal carriages, and equipment necessary for sick-rooms and for the treatment of a patient whilst bed-ridden at home. Referring to the plea of Mr. Clitherow for the inclusion of nurses and health workers in regard to consumption and other diseases arising from their work in hospitals, Mr. Lindgren said there were great difficulties in making provision for health workers within workmen's compensation measures because of the incidence of the diseases with which these workers dealt and because of lack of proof that diseases arose out of or in the course of their employment. The Minister would desire, if possible, to provide for the workers and would like to have discussions between the Ministry of Health, the Ministry of National Insurance, and those who could speak on behalf of persons engaged on such work to see whether it was possible to bring them in.

The debate was adjourned until Oct. 11, when after further discussion the Bill was read a second time and was sent to a Standing Committee.

Medical Officers in the B.L.A.

In a reply to Sir John Mellor Mr. BEVAN agreed that in August the B.L.A. had one medical officer for 409 officers and other ranks compared with one general practitioner for 2,576 civilians in the United Kingdom. He added that the civilian position could be remedied only by acceleration in the rate at which doctors were released from the Services. The Government was urgently considering to what extent this was practicable.

Compensation for Medical Practices

Mr. YORR on Oct. 11 asked the Minister of Health to state the intentions of the Government in regard to compensation for medical practices if taken over under the National Health Service. He also pressed for a general statement in regard to medical practices, in order that demobilized doctors may decide whether to purchase practices.

Mr. BEVAN said that he had this matter under immediate review. He was not yet ready to make any statement, but knew the urgency and would do so as soon as he could.

Experimental Health Centres

Mr. DUMPLETON suggested on Oct. 11 that the Minister of Health pending the establishment of a National Health Service, should initiate experimental health centres in suitable places.

Mr. BEVAN did not think it would be practicable to make this provision in advance of the new legislation. He added he was pressing on rapidly with the preparation of the Health Services Bill, which would deal fully with the subject.

Working Conditions for Nurses

Mr. DUMPLETON asked on Oct. 11 what steps the Minister of Health proposed to take to improve the bad working conditions and hours of nurses in hospitals and institutions.

Mr. BEVAN did not accept the implication that bad working conditions for nurses in hospitals and institutions were general. Where they existed they were in large part due to the effects of the war. He was giving this matter most earnest consideration in consultation with Mr. Isaacs and with the bodies principally concerned. He hoped to make a full statement within the next few weeks.

Release of N. Ireland Doctors—Dr. LITTLE on Oct. 11 urged the Minister of Health, in view of the shortage of doctors in Northern Ireland, to release at the earliest moment doctors who volunteered their services for the duration of the war. Mr. BEVAN replied that the question of the acceleration of the release of doctors from the Services is at present under urgent consideration.

Medical News

A meeting of the Medico-Legal Society will be held at 26, Portland Place, W., on Thursday, Oct. 25, at 8.15 p.m., when Dr. W. Norwood East will deliver his presidential address on "Society and the Criminal."

The programme for the annual meeting of the British Orthopaedic Association to be held at the Royal College of Surgeons, Lincoln's Inn Fields, on Oct. 26 and 27, includes the presidential address by Mr. St. J. D. Buxton on prevention of accident and limitation of injury, a symposium on some methods of treatment of simple extra-articular fractures of the femur, and a lecture and demonstration on clinical photography. The papers are as follows: Prof. T. P. McMurray, Thomas and his splint; Mr. C. H. Cullen, infection of gunshot wounds with actinomycetes; Prof. H. J. Seddon, another island epidemic of poliomyelitis; Prof. J. Leveuf, primitive congenital subluxation of the hip; Mr. J. S. Batchelor, congenital dislocation of the hip; Mr. E. W. Bintliffe, pollicization of the index finger for traumatic amputation of the thumb; Squad. Ldr. E. Somerville, air arthrography of the knee-joint; and Prof. H. Platt, the place of orthopaedics in medical education and in the regional hospital service. The Association will hold its annual dinner in the Hall of Lincoln's Inn on Friday, Oct. 26, at 7 p.m.

The annual general meeting of the London Association of the Medical Women's Federation will be held at B.M.A. House, Tavistock Square, W.C., on Friday, Oct. 26, at 8.30 p.m., when Dr. Beryl Harding will deliver her presidential address on "Relief Work in Greece."

The first meeting of European pharmacists since the war is being held in London next month on the invitation of the Pharmaceutical Society of Great Britain. The members of the Bureau of the Fédération Internationale Pharmaceutique who will attend are: Dr. E. Høst Madsen, Copenhagen, president; Mr. E. Saville Peck, M.A., Cambridge, vice-president; Prof. D. Van Os, Groningen, Holland, vice-president; Dr. T. Potjewijd, Winschoten, Holland, secretary; and M. C. Moyens, Brussels, assistant secretary.

Dr. Elsie Violet Crowe, F.R.C.S.Ed., has been released from internment in Japanese hands.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales only two diseases had totals that differed appreciably from the previous week's return—scarlet fever with 148 more notifications, and whooping-cough with 173 fewer.

A slight rise in the incidence of scarlet fever was fairly general throughout the country; the largest local rises were Yorkshire 33, and Lancashire 25. The drop in the incidence of whooping-cough was due to the experience of a few counties; the largest falls were London 38, Middlesex 34, Warwickshire 33. Although there were only 10 fewer notifications of diphtheria than in the preceding week, there were wide variations within the counties. There were fewer notifications in Lancashire by 28, and in Durham by 23, but the total for London, Middlesex, and Essex was 29 in excess of the previous week's, and reached the highest level recorded this year. The other notable increase in diphtheria was in Glamorganshire, 16.

There were 6 fewer notifications of dysentery. Relatively large local outbreaks were recorded in Dorset, Poole M.B. 18; Yorks North Riding, Middlesbrough C.B. 18; Somerset, Taunton R.D. 14. The other large returns were in London 52, Lancashire 30, Surrey 20, Essex 16, and in Suffolk 15.

In Scotland the chief feature of the returns was a decrease of 33 in the incidence of dysentery; this fall was general except in Glasgow, where there was a slight rise from 55 to 57. The only change in the trends of diphtheria was a rise of 7 in Glasgow.

In Eire the number of cases of diphtheria fell by 8, and that for whooping-cough by 26, while rises were recorded for scarlet fever 13, and measles 8. Notifications of enteritis and diarrhoea increased by 9 cases to 110, of which 84 were recorded in Dublin C.B.

In Northern Ireland there was a further small rise in the incidence of scarlet fever; 17 of the 42 cases were notified in Belfast C.B.

Week Ending October 6

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,683, whooping-cough 909, diphtheria 479, measles 367, acute pneumonia 377, cerebrospinal fever 38, acute poliomyelitis 29, dysentery 207, paratyphoid 11, typhoid 15.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Sept. 29.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to movements of population, birth and death rates for Northern Ireland are still not available.

STATRILIZED MORPHINE

THE SPECIAL (Novutox) COLD STERILISING PROCESS by which statrilized solutions are prepared, offers for Morphine Therapy an advance which is outstanding compared with any other system. Statrilized solutions are • AUTOGENOUSLY STERILE • READY FOR INSTANT USE • LESS TOXIC and are available in Bottles, Ampoules and the new Cartridge pack—the latter providing a fresh container for each patient and being made ready for injection in an instant.

STATRILIZED DRUGS Now Available:	CARTRIDGES 20 x 1 c.c.	AMPOULES 12 x 1 c.c.	BOTTLES 12 c.c./24 c.c.
Morphine 1 gr. per c.c. ..	9/-	4/9d.	3/4d. 4/6d.
1 gr. per c.c. ..	9/3d	5/-	3/6d. 4/9d.
or 1 gr. per c.c. ..	10/6d	5/9d.	4/- 5/6d.
Morphine 1 gr. per c.c. cum ..	10/4d.	5/7d.	3/11d. 5/4d.
Atropine 1/150th gr. per c.c. ..			
Morphine 1 gr. Strychnine 1/160th gr. ..	10/4d.	5/7d.	3/11d. 5/4d.
Atropine 1/100th gr. per c.c. ..			

Each c.c. of statrilized solution contains, in addition to the stated drugs, 0.00002 gr. capryl hydrocupreinatoxin hydrochloride.

Symptomatic Relief

During the next few months there will be an increase in affections of the Respiratory Tract.

CHEST COLDS TONSILLITIS TRACHEITIS BRONCHITIS PNEUMONIA PLEURISY

Many clinicians have recognised the value of externally applied moist heat in relieving the troublesome symptoms so often present in these conditions.

COUGH RETROSTERNAL TIGHTNESS MUSCULAR & PLEURITIC PAIN SORENESS OF THE CHEST

ANTIPHLOGISTINE as a medicated poultice offers a convenient easy-to-apply method of getting moist heat to the affected area. It may be used with Chemotherapy or other special medications. ANTIPHLOGISTINE, due to its formula, maintains moist heat for many hours.

FORMULA

Glycerinum	45.000%	Methylum Ess	00.002%

NORTHWOOD

MIDDLESEX

INCREASED PREVALENCE OF HYPERACIDITY

The influence of war-time conditions is responsible for the marked increase in the number of patients presenting symptoms of gastric upset.

Generally the sufferer gives a history of hurried meals at irregular hours, with a stress factor arising from long hours of work and restricted relaxation.

Milk of Magnesia* is invaluable in securing rapid control of discomfort and distress. Composed of a colloidal suspension of magnesium hydroxide, it soothes the inflamed mucosa, neutralizes the excess acid without liberation of gas, and its mild laxative action ensures removal of toxic waste products.

Milk of Magnesia* may confidently be prescribed in the mild case of dyspepsia or the acute ulcer stage where sustained alkaline treatment is necessary.

Milk of Magnesia contains a proximate 8.45% Magnesium Hydroxide in colloidal suspension.

'MILK OF MAGNESIA'

THE CHAS. PHILLIPS CHEMICAL CO., LTD.,
179, Acton Vale, London, W.3.

Milk of Magnesia is the trade mark of Phillips' preparation of Magnesia.

Maintaining the economic usefulness of the EPILEPTIC PATIENT

'Prominal' is well tolerated, and patients are frequently able to continue undisturbed in their normal occupations.

The hypnotic effect of 'Prominal' is minimal (an advantage over other barbiturates) and secondary reactions are seldom encountered.

Issued in tablets
gr. ½, bottles of 30, 100, 500 and 1,000
gr. 1, bottles of 100 and 1,000
gr. 3, tubes of 10, bottles of 100, 250 and 1,000

MAGSORBENT

Magsorbent, the original and standard brand of synthetic hydrated MAGNESIUM TRISILICATE, is the safe and effective ANTACID for the treatment of Chronic Peptic Ulcer, Hyperchlorhydric Dyspepsia and Acid Fermentation. Magsorbent exerts a sustained neutralising action, it cannot produce toxic alkalosis, and it is also a powerful adsorbent.

FORMULA:—
Magnesium Trisilicate 100%

SORE THROATS

THRO-TIMEX HAVE A RANGE OF LOZENGES TO COVER ALL THROAT NEEDS

* **TROCH. THRO-TIMEX.** These Lozenges are prepared in a pleasant base to produce a local concentration of Sulphanilamide where the infection is greatest—the tonsils and the fauces. Thorough investigation has shown that such local action is of curative and prophylactic value (B.M.J., vol. 2, 1943, page 452).

Formula: Sulphanilamide 0.065 gm.

* **TROCH. THRO-TIMEX 3. (Surface Anaesthetic)**
This Lozenge contains Nupercaine. The prolonged anaesthesia makes it extremely useful in painful tonsillar affections, and after tonsil operations, enabling the patient to swallow in comfort. It is also indicated in bronchoscopy, etc.—or when examining a sensitive larynx.

Formula: Nupercaine 1.25 gm.

TROCH. THROTExA. This Lozenge contains Extract of Krameria, which is a powerful astringent and of special efficacy in cases of sore, relaxed throats and husky voices.

Formula: Extract of Krameria 0.65 gm.

* Prescription only—in a lozenge basis.

ANY QUESTIONS?

Gymnastics for Young Children

Q.—At what age should a child undertake gymnastics at school? Is there any truth in the idea that this form of activity has a harmful effect on a young child?

A.—Gymnastics—by which term should be understood systematic activities—adapted to the age and physical capabilities of the pupils concerned form an integral part of the physical education scheme in all types of schools. Gymnastics include free and informal movements—e.g. those of a game-like character—as well as a wide range of free-standing exercises, and exercises on selected apparatus, carried out in accordance with a predetermined pattern and designed to aid healthy growth and development. Educational gymnastics have nothing in common with the type of work performed on horizontal and parallel bars, and popularly referred to as "German gymnastics".

Gymnastics can be safely and beneficially taught to the youngest pupils, though in the early age groups they appropriately take the form largely of play movements, utilized and controlled in such a way as to add to the value and enjoyment of these movements, while at the same time training the body and mind to respond to external suggestions and stimuli. They thus lead up to the immediate and more accurate physical and mental response expected from older children. Moreover, the youngest pupils, under a suitably trained teacher, can derive pleasure and profit from such basal movements as hanging, swinging, and climbing on apparatus devised for the purpose.

Gymnastics, interpreted as described above, can have no harmful effect on young children, on the contrary, they can contribute powerfully, under competent direction, to health and happiness.

Putrefaction of Meat, Poultry, and Game

Q.—Before the discovery of penicillin it was common knowledge that putrid cheese could be eaten with impunity. The same applies to putrid game, such as grouse and partridge, while ordinary meat or poultry could not be eaten in the same stage without danger. It has often struck me that there must be something inimical to ordinary putrefactive bacteria in the decomposition of game. What are the organisms concerned in the putrefaction of game? Has the question of its possible bactericidal or bacteriostatic effect ever been investigated?

A.—The inquirer poses a question, but also makes statements which are not altogether accurate. Putrefaction is a complicated process due to the action of many bacteria, some of which are aerobic organisms, but the main activities are due to putrefactive anaerobes. None of these organisms is pathogenic to man, and there is no evidence that the consumption of food—whether it is meat, game, poultry, or cheese—in a state of early decomposition is harmful to man, provided no pathogenic organisms are present in addition. The putrefactive changes develop rather differently in the types of food mentioned, due partly to differences in composition, including their water content, but these changes are all of the same order and due to non-pathogenic bacteria. The suggestion made that meat is dangerous if it shows putrefactive changes is still widely believed on the basis of the old idea that food-poisoning is due to ptomaines, but the conception of ptomaine poisoning is completely exploded. (See *Journal*, Jan. 6, 1945, p. 32.)

It is true that meat which is showing even incipient decomposition changes is condemned, but this action is based on the fact that the animals which supply the meat are liable to be infected with *Salmonella* and other pathogenic bacteria associated with food-poisoning, and it is a reasonable assumption that if meat exhibits such changes it has been badly looked after and that, if pathogenic organisms were present, they would have opportunities to multiply and generally infect the meat. With game and poultry the risk is

slight, but here again the sale of such food showing decomposition changes would not be permitted.

These considerations suggest no reason to suppose that there are any substances in game which are deterrent to bacterial growth, as all the facts are fully explainable on other grounds.

Capillary Naevus

Q.—Is a capillary naevus due to some intra-uterine arrest of development, or is it a hereditary recessive Mendelian characteristic? If both parents have naevi, are the children likely to be free?

A.—This is certainly not a recessive Mendelian characteristic. In fact the indications for any hereditary basis are very slight. On general principles it might be anticipated, perhaps, that a general tendency to the formation of such naevi was heritable, but it is likely that non-genetic accidents of development are much more important than any such hereditary tendency in determining the actual appearance of a port-wine mark. It has been noted that the naevus often has a segmental distribution, and it may be secondary to some abnormality of the nervous system. So far as present knowledge extends, it seems probable that the child of two affected parents would run little more risk of being similarly affected than any random unselected child in the general population.

Vitamin B in General Therapy

Q.—Could you please give a concise account of the indications, and if possible the rationale, for vitamin B therapy, which seems to be prescribed for so many varied complaints? I am not including deficiency diseases.

A.—Vitamins of the B group may be used rationally in treatment of conditions (as distinct from frank deficiency diseases) which are known to be caused in human beings by deficiency of these vitamins. For example:

Vitamin B (Aneurin).—Anorexia, constipation, tingling of hands and feet, aching muscles (especially calf muscles), changes of temperament (which may be called neurosthenic), bilateral neuritis, oedema and tachycardia without obvious cardiac lesions.

Niacine (Nicotinic Acid or Nicotinamide).—Diarhoea, changes of temperament such as morbid anxiety or fear, stomatitis (including Vincent's infection).

Riboflavin.—Correal vascularization. Wills has shown that a nutritional macrocytic anemia is cured by crude liver extract or marmite, but not by the purified extrinsic or intrinsic factors, nor any of the known components of the B complex. Anamiasis should be given whenever the diets used in treatment are likely to be deficient—for example when febrile patients are given large doses of glucose.

These vitamins may be used to treat conditions which are considered to resemble those that occur in deficiencies in animals. Aneurin has been used in treatment of Wernicke's syndrome on the ground that haemorrhagic lesions in the basal ganglion and brainstem occur in pigeons on a diet deficient in aneurin. However, Joliffe et al. reported a large series of cases of "nicotinic acid deficiency encephalopathy" which resembled Wernicke's syndrome in their clinical picture. Joliffe found that aneurin had no effect in these cases and that nicotinic acid caused rapid improvement.

Choline and vitamins of the B group protect animals against liver damage; hence choline and concentrates of the B group have been used in treatment of cirrhosis of the liver, and good results have been claimed. On the ground of its vasodilator action, nicotinic acid has been used in treatment of Ménière's syndrome.

There is no evidence that these vitamins will benefit patients with gastric ulcer if their diet is not inadequate. Their use for various neurological conditions is based on the belief that they have some general "protective" action on the nervous system.

Vitamins of the B group are employed extensively on the ground that they may do good and can do no harm. This may be justifiable; however, recent studies suggest that the administration of large doses of a single vitamin may provoke deficiency of another vitamin. If these vitamins are given, concentrates containing all the possible members should be used.

Variations in Pulse Rate

Q.—A man aged 60, past history no serious illnesses other than two periods of low blood pressure which were corrected with rest and treatment. Present condition: heart clinically and electrocardiographically normal. B.P. 145/88. Pulse rate varies between 60 and 40 beats a minute. What is the reason for this, and what treatment might be tried?

A.—Variations in the pulse rate between 40 and 60 a minute may be due to a high vagal tone—that is, presuming that the pulse rate is really the heart rate and that no beats occur at the heart which do not reach the pulse. The normal electrocardiogram has excluded complete heart-block. It is not clear whether the patient feels at his worst when the pulse is slow or quick. If vagal influence is to be got rid of, then full doses of atropine in some form should be made use of. If such variations in rate are the only abnormality

to be detected in the heart, then one need not restrict activity; probably exercise would improve the patient. It would be worth while knowing whether the blood pressure varied with the rate of the heart. It might be well to try full doses of strychnine, or some stimulant of the sympathetic such as ephedrine or amphetamine.

Treatment of Eclampsia

Q.—What is the modern treatment of eclampsia, occurring before the onset of, and during, labour?

A.—The modern treatment of eclampsia is based largely on the views of Stroganoff. It is believed that the danger of the condition depends on the number of fits, and that external stimuli are important in the causation of fits. The treatment, therefore, consists in placing the patient in a quiet, darkened room, reducing external stimuli to the minimum, and giving sedatives to lower the sensitivity of the central nervous system. Paraldehyde is preferred as a sedative in many clinics and is given per rectum in a dose of 6 drachms, repeated in 4 hours and again in 6 hours. If the patient is restless, morphine with atropine may be given in addition, but large doses of morphine should be avoided. Expectant treatment is advised in most cases of eclampsia occurring before labour, though pregnancy should be terminated within a day or two after the fits are controlled.

When eclampsia occurs during the course of labour the membrane should be ruptured when the cervix is half dilated. When the cervix is fully dilated forceps delivery should be employed. Any obstetric abnormality should receive the appropriate treatment. Caesarean section may occasionally be the treatment of choice, especially after the fits have been controlled in a case where the child is alive and viable. Caesarean section may also be needed in cases of severe eclampsia where medical treatment fails to control the fits.

The above is only an outline of the principle of the modern treatment of eclampsia. For a more detailed answer, and for special methods of treatment, the questioner is referred to *Antenatal and Postnatal Care*, by Prof. F. J. Browne (5th edition, Churchill, London, 1944, pp. 377 *et seq.*).

Pruritus and Glycosuria

Q.—A woman of 33 has suffered from severe pruritus vulvae for over five years. In January and April, 1945, urine examination gave +++ result for sugar. Within the last six months she has lost about 10 lb., feels nervous and shaky, easily exhausted, and has great craving for sweets and bread. Urine now free; blood-sugar-tolerance curve: fasting 83 mg., half an hour after glucose 160 mg., 1½ hours after glucose 100 mg., two hours after glucose 87 mg. (capillary blood findings). Is it likely that an undue amount of sugar is present in the tissues of the vulva and gives rise to irritation? If so, should insulin be used in small doses to assist the synthesis of glycogen in liver and muscle and to reduce the amount of sugar in the tissues? The restriction of carbohydrates in the diet is difficult because of her craving for them and the loss of weight.

A.—This question is difficult to answer satisfactorily and some further information is needed about the diet. The sugar tolerance is normal and consequently excludes the diagnosis of diabetes mellitus. It is possible that the present diet is very low in carbohydrate and that the patient has a mild diabetes which has recovered with dietetic treatment. If so the pruritus should have disappeared, and it does not seem likely that it is in any way connected with glycosuria. There is no evidence to suggest that there is any difference between the sugar content of the vulval tissues and that of the blood. If the diet contains less than 150 grammes of carbohydrate it should be increased to 200 or 250 grammes, as the patient is losing weight. If glycosuria returns and a high blood sugar is confirmed, insulin should be given in adequate amounts. It is suggested that another cause for the pruritus should be sought.

Tenderness of Muscles

Q.—For more than three years a patient has suffered from tenderness of the voluntary muscles. At times the slightest pressure on a muscle gives intense pain. Sometimes there is aching, but usually there is pain only on pressure. A slight pinch produces agony. His general health is good. What might be the cause?

A.—It is difficult to refer these symptoms to any recognizable lesion of the neuromuscular system. It is assumed that care has been taken to exclude peripheral neuritis and also occupational disease; puzzling symptoms are sometimes produced by chemicals used in industry. It is equally difficult to attribute the symptoms to neurasthenia, for, although they might be affiliated with the "rheumatism" and "fibrositis" of neurasthenia, the other symptoms of that disorder are apparently absent. The systematized pattern of the complaint suggests an underlying physical or biochemical abnormality. Biopsy of muscles is easily performed and might provide information of value in this patient. An x-ray examination of the muscles for parasites, calcification of ligaments, etc., might also be helpful. The blood chemistry should be investigated, particularly the blood sugar, serum calcium, and erythrocyte sedimentation rate. If none of these investigations gives a clue to the

cause, symptomatic treatment with the vitamin B complex should be tried, including large doses of B₁. Wide-field irradiation with ultra-violet or infra-red rays might also give relief.

LETTERS, NOTES, ETC.

Venerology

Brigadier T. E. OSMOND, Honorary Consultant in Venerology to the Army, writes: As I was mainly responsible for the introduction of the word "venerologist" into "Army medical jargon" I feel it incumbent on me to answer the letter of Lieut.-Col. Henry Richards (Sept. 22, p. 414). It must be admitted that the word is a hybrid, but "English contains thousands of hybrid words, of which the vast majority are unobjectionable" (Fowler: *Modern English Usage*, p. 241). In any case "venerologist" is preferable to "dermatologist," which it supplanted. But the difficulty lies deeper; the term "venereal disease" officially refers to syphilis, gonorrhoea, and soft chancre, yet many patients suffering from these diseases may be excused from "venery." For many years doctors have been searching for a more suitable word than "venereal" but without success. Parenthetically an "-ologist" is a person who makes a study of a subject but is not necessarily an "expert practitioner" in it. Criticism, to be of value, should be constructive: Col. Richards's seems to be destructive. Having forgotten much of the classics which I learned at school I consulted a friend who is an eminent classical scholar. He admitted that he found the problem difficult, but tentatively suggested "aedeologist," from the Greek αἰδῶ, or "aphrodisiologist" from ἀφροδῖσιος; either word can mean pudenda. Admittedly neither word contains any reference to disease, but nor do ophthalmologist or laryngologist. It is to be feared that neither of the words suggested will prove acceptable, but can Col. Richards or any of your readers suggest a better?

Digestive Disorders and Swallowed Sputum

Dr. P. A. GALPIN (Plaistow) writes: With reference to the question and answer on digestive disorders and swallowed sputum (Sept. 8, p. 341), from the reply given is one to assume that there is no risk to patients suffering from chronic sinusitis or bronchiectasis in swallowing muco-pus, and that one can trust the gastric secretions to deal with any infection? From my own experience I have noted many children suffering from post-nasal catarrh, who have not learned to spit, frequently have nausea or abdominal pain. In my opinion this has been due to swallowing muco-pus, and I have therefore endeavoured to persuade the parents to train the children to avoid swallowing muco-pus—in other words, to learn to spit. Two or three questions come to one's mind. Which is the factor in gastric secretion which has bactericidal properties? Is it hydrochloric acid? If this is so then patients with hypochlorhydria are at a definite disadvantage, and it would seem to me that patients debilitated after acute catarrhal conditions following measles or whooping-cough may be producing gastric juice deficient in bactericidal power. The surgeon has great faith in the bactericidal power of the peritoneum, but he does not willingly allow abscesses, whether acute or chronic, to spill over in the peritoneum.

Neutralizing Gastric HCl

Mr. E. H. JOHNSON and Mr. J. DUNCAN write: The treatment of peptic ulcer as described in your "Any Questions?" page of your issue of Sept. 1 mentions the importance of maintaining a stomach acidity in the region of pH 3.5 in order to promote healing of the ulcer by the inactivation of the pepsin. The maintenance of this continued neutrality can be accomplished by adequate dosage of aluminium hydroxide. Aluminium hydroxide alone of the common antacids possesses the property of neutralizing the gastric hydrochloric acid to a maximum pH of 3.5 to 4.0; excess dosage after the initial neutralization serves to maintain this favourable condition by the neutralization of further secretion. This important property of aluminium hydroxide was indicated in a recent paper upon the "Chemical Testing of Antacids" given by us at the British Pharmaceutical Conference held on July 18, 1945.

Early Treatment of Bell's Palsy

Dr. J. L. THOMAS (Brynawr) writes: The article by Mr. H. P. and Dr. Cecily Pickerill on the above subject (Oct. 6, p. 457) recalls with interest that, about fifty years ago, while in colliery practice in Glamorganshire, I had a case of Bell's palsy (catarrhal) in a young miner who was a promising public singer. While assiduously, but ineffectively, treating the case electrically, by good fortune I read of Robert Jones—always a friend of weak muscles—using in such a case mechanical means to draw the sound side of the face towards the paralysed one. I resolved to imitate his treatment by using strips of plaster, and after one month the result was highly successful—and very cheering.

Corrigendum

By a slip of the pen the title of Wing. Cmdr. Kenneth Bergin's letter (Oct. 13, p. 508) was made to refer to the Army; the heading should have read: "Psychiatry in the R.A.F."

BRITISH MEDICAL JOURNAL

LONDON SATURDAY OCTOBER 27 1945

THE INCIDENCE AND CAUSES OF BLINDNESS IN THE BRITISH COMMONWEALTH

BY

ARNOLD SORSBY, M.D., F.R.C.S.

Research Professor in Ophthalmology, Royal College of Surgeons of England and Royal Eye Hospital

Only a tentative estimate of the number of blind and the barest of assessments of the causes of blindness in the British Commonwealth as a whole are possible. Fairly complete data are available for England, Wales, and Scotland, but those for other parts of the Empire vary between being relatively adequate to negligible. Any final analysis is therefore out of the question.

1. THE NUMBER OF BLIND

The two fundamental difficulties in assessing the number of blind are the lack of a universally accepted definition of blindness and the lack of uniformity in the methods employed for collecting blind statistics.

In the census returns of most countries information is sought on physical and mental infirmities in the population. Those totally blind are asked to declare this fact. The census returns therefore deal with total blindness as determined by a lay assessment. A lay assessment also enters largely into the statistics supplied by voluntary agencies caring for the blind, though total blindness is not generally the only criterion used by such agencies in granting benefits. Statistics from such sources are far from comprehensive, as they deal with only that section of the blind population which seeks charitable relief, and their extent is, moreover, determined by the energy and resources of the agency in question. Furthermore, lay assessment is still the general rule and appears to be particularly capricious when total blindness is no longer the criterion.

In contrast to these two distinctly fallible methods is the one that has emerged only recently as a result of the administration of the Blind Persons Act of 1920. Under this Act statutory benefits were made available to the blind in England, Wales, and Scotland, admission to the Register being obtained on medical certification—which of late has generally meant certification by an ophthalmologist. The data thus obtained have therefore considerable uniformity, but still cover only those who seek the statutory benefits that the Act allows. The fundamental difficulty as to what constitutes blindness is masked rather than solved by the statutory definition of "so blind as to be unable to perform any work for which eyesight is essential." In practice this has been interpreted—somewhat arbitrarily—to mean vision of 3/60 or less with a full field, or better central vision when associated with specified field defects.

For England, Wales, and Scotland data on medical certification by a definite, even if controversial, standard are thus available, and these data are limited only by the fact that not all blind persons seek certification. Elsewhere census returns are still the main source of information, but for some years now there has been considerable criticism of such returns. The data thus obtained have come to be regarded as so unreliable as not to be worth the trouble of collecting, and inquiries for personal infirmities have been discontinued in the censuses for 1921 and 1931 in Great Britain and in that for 1940 in the U.S.A. None the less census data are the fullest that are available for the greater part of the Commonwealth, and critically interpreted they are of considerable value, as will be shown in what follows.

British Isles

England and Wales.—In 1911, when the last census which sought information on infirmities was taken, there were 26,336 persons who declared themselves totally blind. When the Register under the Blind Persons Act was established there were found to be 25,840 eligible—a close approximation to the census figures. The number of registered blind has, however, increased steadily year by year, as the following figures show:

Year	Number on Blind Register	Year	Number on Blind Register
1920	30,785	1933	63,408
1921	34,894	1936	67,534
1923	36,518	1938	71,875
1925	42,140	1940	74,418
1927	46,822	1942	75,306
1929	52,727	1943	76,507
1931	60,593	1944	76,125

There is, of course, no reason for believing that the incidence of blindness has increased during 1920–44 in the startling proportions suggested by these figures; these merely represent an increasing efficiency in the registration of the blind. They furthermore indicate that registration has become fairly effective during recent years. It is also clear that the census figures were a gross underestimate, but it must be borne in mind that the criteria of blindness adopted for these two different returns were different: for the census it was total blindness, for the purpose of the Blind Persons Act it was—in practice—3/60. That the census returns were not quite meaningless is shown by the following findings. An analysis of 9,522 blind certificates in the Curries of London and Middlesex (Sorsby, 1945a) showed that 1,013 were totally blind and 1,822 had perception of light only. The rest mostly had vision up to 3/60. Thus some 2,835 qualified for what a layman would regard as total blindness, making 29.9% of all registered blind in these areas. If it is taken that 30% of all the registered blind in the country are blind in the sense indicated (i.e., no perception of light and perception of light only), an incidence of blindness approximating that shown by the census figures of 1911 is obtained. It is impossible to assess the number of blind persons who have not sought registration. At hospitals one still sees certifiably blind patients who have not been registered, while an unknown proportion for various reasons decline certification. It is safe to conclude that the number of blind people in England and Wales is not less than 80,000 and is unlikely to exceed 100,000.

Scotland.—The census for 1911 showed 3,317 blind persons in a population of 4,760,904 (or 70 per 100,000). The number of registered blind persons was 4,104 in 1919—a close approximation, as in England and Wales, to the census figure. But again as in England and Wales it has risen steadily, the rise being confined to the years up to 1929.

Year	Number on Blind Register	Year	Number on Blind Register
1919	4,104	1933	8,675
1921	5,138	1936	8,500
1923	5,754	1938	8,973
1925	6,332	1940	8,038
1927	6,939	1942	8,891
1929	8,518	1944	8,804

The Dominions

Canada.—The census figures for 1931 showed 7,343 blind persons in a total population of 10,376,786 (or 71 per 100,000). Statutory benefits for the blind were introduced by Act of Parliament in 1937, and by July, 1938, there were over 3,000 applicants for blind pensions. This was distinctly less than the 4,712 blind on the registers of the Canadian National Institute for the Blind in 1927, but the number of registered blind (? under the Act of 1937) had risen to 12,854 by 1944. It would therefore seem that in Canada the experience of England and Wales is being repeated, and that the number of registered blind is likely to increase. In Newfoundland the number of registered blind in 1944 was 219. The 1911 census showed 287 blind in a population of 242,619 (118 per 100,000).

South Africa.—In an official inquiry carried out in 1936 concurrently with the census there were 1,624 blind amongst the white population of 2,003,857, or 81 per 100,000. No adequate data are available for the coloured population: the same inquiry covering 769,661 coloured persons, excluding Bantu and Asiatics, showed 981 blind (127.7 per 100,000). At the end of December, 1940, the South African National Council for the Blind had detailed information regarding 17,263 blind persons in the Union: there were 1,828 Europeans, 1,632 coloured, and 13,803 natives. Since then, and especially since 1942, when the payment of an increased grant to blind natives was introduced, the Council has been "inundated with registrations of blind natives and the total had increased by leaps and bounds." Recently the Act allowing grants to blind people has been amended to include Indians. There is as yet no information as to the number of blind Indians in the country. By December, 1943, the total number of registered blind had risen to 30,834, and consisted of 2,103 Europeans, 1,887 coloured, and 26,844 natives. On the basis of an estimate of the population supplied by the Director of Censuses the rate per 100,000 at the end of 1942 for the three different communities was: European 91, coloured 211, natives 351.

Australia.—The 1933 census for the Australian Commonwealth showed 3,898 blind in a population of 6,229,839 (63 per 100,000).

New Zealand.—The census for 1916 showed 570 blind in a population of 1,009,449. The New Zealand Institute for the Blind in 1936 estimated the number of blind at 1,000 for the whole country, or 70 per 100,000 (against 56 shown by the census of 1916). It had records of 720 blind, and of these 688 were totally blind (It is unlikely that with 688 known cases of "total blindness" the total number of blind, by English standards, would be only 1,000).

The total white population of Canada, Newfoundland, South Africa, and Australasia is of the order of 20 millions. The census rates of blindness per 100,000 were 71 for Canada (1931), 118 for Newfoundland (1911), 81 for South Africa (white population, 1936), 63 for the Australian Commonwealth (1933), and 56 for New Zealand (1916). These are not dissimilar from the census rate of 73 for England and Wales and 70 for Scotland in 1911. If it is concluded, on the strength of experience in England and Wales since the working of the Blind Persons Act, that the actual rate is about 200-250 per 100,000 (on the basis of a computed number of 80-100,000 blind in a total population of 40,000,000), the total of blind amongst the white population of the Dominions is of the order of 40-50,000.

Other Possessions

India.—The census for 1931 showed 606,360 blind in a population of 352,837,778—a rate of 172 per 100,000. It is generally agreed that this is a considerable underestimate. If the rate of blindness known for England and Wales applied to India, its population of over 400,000,000 would provide 800,000 to 1,000,000 blind. But blindness in India is far more common than in England and Wales, and it appears that Indian census figures on blindness are grossly vitiated by the widespread illiteracy and by superstitious fears. On studies undertaken in selected areas both Henderson and Kirwan hold that the census figures indicate only one-third of the blind in India; Megaw puts it as low as one-quarter. Moreover, even these observers, in speaking of blindness, use a considerably lower

criterion than that now used in England—i.e., counting finger at one metre instead of 3/60. At the very least the census figure of 606,360 must therefore be multiplied by three or four. This gives the number of those totally or subtotally blind at between 2 and 2½ millions. For the present this must be accepted as a minimum figure. The actual number is likely to be considerably more, for India is one of the classical countries of blindness, and according to O'Dwyer "there is no country in the world to-day where the affliction of blindness is so widespread." This being so, a comparison with Egyptian and Palestinian figures rather than with those for England and Wales is called for. In both Egypt and Palestine the census figures indicate a rate of blindness 10 to 15 times that for England and Wales. On that basis the blind in India number between 10 and 15 millions.

Ceylon.—The census for 1921 showed 4,005 blind in a population of 4,498,605—a rate of 89 per 100,000. There is no reason for believing that the situation in Ceylon is substantially different from that of India, and the census figure must be regarded as a serious underestimate.

Egypt.—The appalling rate of 1,325 blind per 100,000 was recorded by the census of 1907. Ten years later it had declined to 1,222, whilst in 1927 it fell to 775 (109,934 blind in a population of 14,177,864).

Palestine.—Palestine has the world's highest census rate for blindness. It was 843 per 100,000 in the 1931 census (817 blind in a population of 969,268), surpassing the rate of 77 recorded for Egypt in 1927. In contrast to the high rate for the Muslims of the country, that for the Jews is relatively low and for Christian Arabs intermediate between the two (Muslim 1,061, Christians 564, Jews 139 per 100,000).

African Colonies.—No adequate data are available for the greater part of Africa. The native population in Uganda in 1911 showed a census rate of blindness of nearly five times that of England and Wales (354 against 73 per 100,000). It is not known whether blindness in the native population in Africa is of the order of frequency seen in India, Egypt, and Palestine. That blindness is extremely frequent, and indeed far more frequent than anywhere else in the world, is suggested by the following findings concerning natives in the Union of South Africa: Rosset-Berdez (1944) in an inquiry for the South African Government examined 4,500 natives; only 527 (13.2%) were normal; 214 (5.3%) were totally blind; 360 (9.0%) had lost one eye as a result of disease.

Pacific Islands.—Information is scanty. The census for 1911 for the Fiji Islands showed 1,385 blind in a population of 137,248, giving a rate of 1,009 per 100,000—i.e., a rate of the order of Egypt and Palestine. It is not known whether the Fiji Islands can be regarded as typical of Indonesia.

It is obvious that, whatever be the definition of blindness, no final assessment of the number of blind in the British Commonwealth is possible. A fairly clear indication is available for the 46,000,000 in England, Wales, Scotland, and Northern Ireland: it cannot be less than 90,000 and is likely to exceed 100,000. For the 20,000,000 whites in Canada, Newfoundland, Australasia, and South Africa the number of blind is likely to be 40-50,000. As for the native populations of the British possessions in Africa, Asia, and Indonesia, their blind would number about 1½ million if blindness were no more common among them than it is in the British Isles and the Dominion, but it is likely that the actual figure is considerably more than 10 millions.

2. THE CAUSES OF BLINDNESS

Data on the causes of blindness in England and Wales and in Scotland are fairly adequate. Elsewhere the information is scanty.

England and Wales.—No less than 77.2% of the 76,500 registered blind in 1943 were over 50 years of age; 20.8% in the age group 16-50 years, and 2.0% in that of 0-16 years. Analyses of the data as to the age at onset of blindness do not affect substantially the outstanding fact that in most cases blindness is an affliction that, in the phrase of the *Iliad*, "comes on the sad threshold of old age." As to the causes of blindness, the Prevention of Blindness Committee (1938) gives an analysis of 5,290 blind certificates and the Northern Counties Association for the Blind (1938) of 10,000 certificates. Both agree

placing cataract first with 25.0% and 33.6% of the total respectively; in both series glaucoma takes the second place with 11.8% and 10.0% respectively. Defects of congenital, hereditary, and developmental origin, and myopia take the third and fourth places in the first series (with 11.0% and 10.2% respectively), and occupy the reverse order in the second (with 7.0% and 8.5% respectively). Taken together, these four causes—cataract, glaucoma, defects of congenital, hereditary, and developmental origin, and myopia—account for 58.0% in the analysis of the Prevention of Blindness Committee and 59.1% in that carried out by the Northern Counties Association for the Blind. Substantially the same result was obtained in an analysis of 9,562 registered blind in the Counties of London and Middlesex (Sorsby, 1945a). Cataract and glaucoma again took the first and second places with 21.2% and 14.0% respectively, whilst myopia accounted for 12.1% and defects of congenital, hereditary, and developmental origin for 10.4%, the total for the four main causes being 57.7%. When this series of 9,562 cases is analysed in age groups a considerably different picture emerges.

(1) In the age group 0-14 years (143 cases) defects of congenital, hereditary, and developmental origin lead with 67.1%, and ophthalmia neonatorum is second with 5.6%, the remaining causes all being considerably less significant.

(2) In the age group 15-29 years (656 cases) defects of congenital, hereditary, and developmental origin still lead with 38.4%, with congenital syphilis in the second place with 14.0%.

(3) In the age group 30-49 years (1,303 cases) the leading cause is still as in the other two age groups, this time with 21.3%, and with myopia in the second place with 15.5%. Congenital syphilis is now third with 13.1%.

(4) In the age group 50-69 years (3,541 cases) myopia leads with 18.6%; glaucoma and cataract come second and third with 15.2% and 14.0% respectively.

(5) In the age group of 70 years and over (3,725 cases) cataract is responsible for 39.3% and glaucoma for 19.3%, with senile macular lesions in the third place with 11.7%.

The numerical frequency of cataract and glaucoma, which is so striking a feature in the statistics for the blind population, gives an exaggerated significance to these two causes. When the causes operative in the different age groups are evaluated in terms of years of expectation of life—i.e., in expected years of blindness—cataract falls from the first place to the third with 13.1% of the total of expected years of blindness, and glaucoma falls from the second to the fourth place with 10.0%. Defects of congenital, hereditary, and developmental origin, which in order of frequency are fourth, now assume a preponderant first place with 22.9%, and myopia takes the second place with 16.0%. The congenital and congenitally determined anomalies (such as myopia) together are thus responsible for no less than 38.9% of the total of expected years of blindness, whilst cataract and glaucoma together, though numerically so outstanding, account for considerably less—viz., 23.1%. On this reckoning congenital syphilis is also a cause of some importance, accounting for 8.8%, with ophthalmia neonatorum not far behind (6.2%). If these provisional data on the blind in London and Middlesex apply to England and Wales as a whole, the major causes of blindness are not cataract and glaucoma but, in order of frequency, defects of congenital, hereditary, and developmental origin, myopia, cataract, glaucoma, congenital syphilis, and ophthalmia neonatorum.

Scotland.—As in England and Wales most of the blind are over 50 years of age (the actual percentage for 1943 being 74.1 against 77.2 in England and Wales). Marshall and Seiler's study of 2,885 registered blind in Glasgow and South-West Scotland places myopia as the first of causes with 15.9%; cataract, chronic septicæmia, glaucoma, and congenital anomalies follow with 15.2%, 10.9%, 8.9%, and 8.1% respectively. Ophthalmia neonatorum occupies the eighth place with 3.4%. Calculated in years of blindness the patients in these different categories had experienced, chronic septicæmia comes first (with an average of 12 years); congenital, hereditary, and developmental anomalies second (11.4 years), myopia third (10.3 years); and ophthalmia neonatorum fourth (10.1 years). Cataract and glaucoma come low with the eighth and tenth place respectively. These findings agree with those for London and Middlesex on the significance of defects of congenital, hereditary, and developmental origin, and of myopia as foremost causes of blindness.

The Dominions.—No adequate data are available. There are various analyses of returns from blind schools and institutions and from records of patients seen by ophthalmologists in practice. They give the impression that in Australia, New Zealand, and Canada, at any rate, the same causes of blindness operate as in the British Isles. Registers of blind persons, comparable in completeness as to numbers and causes, do not appear to be available for any of the Dominions, except possibly South Africa. Here a register in the process of formation provides data on the causes of blindness in 26,844 natives and 2,103 whites registered by December, 1943. The main causes recorded were:

	White (2,103 Cases)	Native (26,844 Cases)
Cataract (senile, traumatic, and unspecified)	9.7	42.6
Syphilis	11.2	5.8
Glaucoma	7.2	5.4
Trachoma	5.0	2.4
Local infections of coats of eye	4.5	8.9
Ophthalmia neonatorum	4.4	0.8
Congenital, hereditary, and developmental defects (including congenital cataract)	20.9	1.2

Without a fuller knowledge of local conditions and the way these data were collected, the interpretation of these findings is difficult. A significant observation is the finding of trachoma in 13% natives out of 10,591 examined in a special investigation (Rosen-Berdez).

India.—Several analyses of the causes of blindness in relatively small series are available. In a series of 2,750 reported by Megaw cataract was responsible for 23%, glaucoma and smallpox for 9.0% each, and trachoma for 8.0%. In a series of 2,044 blind eyes Gnanadikam found that among these blind in both eyes the order of frequency of the causes was glaucoma, corneal ulcer, keratomalacia, trachoma, iritis, smallpox, and gonorrhoeal ophthalmia. Another observer (Bagchi) gives the following order of frequency in 3,404 persons blind in one or both eyes: anterior staphylococci, 39.7%; trauma, 7.0%; trachoma, 6.2%; leucoma, 5.9%; keratomalacia, 5.8%. In 74 inmates of the Calcutta Blind School Indra found the following distribution: congenital, 15 cases; smallpox, 11; syphilis, 10; ophthalmia neonatorum, 5; keratomalacia, 4—the last being regarded as an underestimate of the frequency of the affection, "as few such children can afford the expenses of the Blind School." Wright (1937) gives the principal causes in order of importance as:

In Children	In Adults
Keratomalacia	Cataract
Ophthalmia neonatorum	Optic atrophy (mainly syphilitic)
Congenital syphilis	Corneal ulcers
Hereditary blinding disease	Glaucoma
	Trachoma

which in both children and adults irritant remedies (the result of ignorance and the lack of adequate facilities for treatment) and smallpox are potent factors. All these assessments have one thing in common: the immense amount of blindness caused by various uncontrolled infective processes and by malnutrition.

Egypt.—In a cumulative list of causes of blindness published in the reports of the ophthalmic hospitals the predominant cause of blindness in some 75,000 cases (7 eyes) are shown as conjunctivitis with corneal complications and its sequelae. Some 82% of all blind fell into this category, and it appears that acute ophthalmia rather than trachoma is the main form of conjunctivitis leading to blindness. Glaucoma is also a cause of some significance.

Palestine.—The reports of the Ophthalmic Hospital of the Order of St. John, Jerusalem, give a parallel analysis to that in the Egyptian reports and the findings are similar. Some 78% of all blindness is caused by conjunctivitis and its corneal complications. Shihab (1937) holds that some 75% of all blindness is caused by the acute ophthalmias, and that the two extremes of age are most susceptible.

Trinidad and Tobago.—In a study of the causes of blindness in 194 patients Métiévier found syphilis the cause in 45 instances, glaucoma in 38, and leprosy in 14. Other significant factors were cataract and purulent ophthalmia.

African Colonies.—Little is known of the causes of blindness in the African colonies. Trachoma is probably rare but not unknown, as was previously believed. Two recent studies have drawn attention to onchocerciasis (Ridley, 1945; Scott, 1945). It is not known whether the incidence and causes of blindness seen in the natives of the Union of South Africa are typical of the African population as a whole.

3. PREVENTION OF BLINDNESS

In England smallpox figured as the main cause of blindness in such assessments as are available for the early years of the last century. Towards the end of the century ophthalmia neonatorum was the largest single cause; in a collective survey carried out by the Ophthalmological Society in 1884 it was found responsible for between 30 and 40% of blindness seen at blind schools and institutions. These findings may be taken as indicative of the role of infectious diseases as causes of blindness in this country during the last century. To-day infectious disease—both exogenous and endogenous—accounts for only a small proportion of all blindness; in the survey for the Counties of London and Middlesex it stood at not much more than 15% (Sorsby, 1945a). Generally speaking, the most significant cause in the undoubted decline in the incidence of blindness in England, and in advanced countries generally, has been the control of infectious disease by public health measures, adequate facilities for treatment, and of late years the advances in chemotherapy, beginning with arsphenamides in the treatment of syphilis. Other causes in the decline of blindness have been the development of ophthalmology, the rise of eye hospitals and eye departments, and the perfection of operative techniques for cataract and glaucoma.

England and Wales.—The decline in the incidence of blindness in England and Wales is hardly reflected by the mounting number of registered blind since 1920. That a decline has taken place is suggested by the census findings since 1851, which have shown a steady diminution in the rate of incidence per 100,000 with each census. The rate in 1851 was 102; it declined to 96, 95, 88, 81, 78 at the subsequent decennial censuses, falling to 73 in 1911. More definite evidence is supplied by the returns for the age group 5-16 years under the Blind Persons Act of 1920. Unlike those for the other age groups, the returns for this group may be taken as giving a true presentation, for children come under the care of the school authorities, and the blind child is unlikely to escape registration. In contrast to the increase in the total number of registered blind, there has been a striking decline in the number of registered blind children, as the following table shows (Sorsby, 1945b).

TABLE I.—Incidence of Blindness in Children aged 5-16 Years, England and Wales, 1823-43

Year	Population aged 5-16 Years	No. of Registered Blind aged 5-16 Years	Rate per 100,000
1823	7,477,143	2,723	36.4
1825	7,306,761	2,720	37.2
1827	7,385,359	2,554	34.6
1829	7,262,590	2,438	33.6
1831	7,166,056	2,355	32.9
1833	7,246,446	2,089	28.8
1836	6,890,730	1,853	26.9
1838	6,694,300	1,676	25.0
1839	•	1,619	24.2†
1840	•	1,499	22.4†
1841	•	1,425	21.3†
1842	•	1,369	20.5†
1843	•	1,355	20.3†

* Population figures not available for publication † On 1938 population figures

A decline to almost a half in the space of twenty-one years is a gratifying testimony to the efficacy of the many measures that are operative in the prevention of blindness. But it cannot be assumed that this trend is applicable to the whole blind population. In fact it is likely to be almost entirely confined to the lower age groups. It has already been seen that the causes of blindness are notably different in the different age groups and that nearly 80% of the blind are over 50 years of age. There is no reason for believing that blindness from cataract, glaucoma, myopia, and senile macular lesions—the causes operative in that age group—is declining to any marked extent, while the evidence available for the causes of the decline in the incidence of blindness in the young indicates that the reduction in them is wholly due to the elimination of the

sequelae of infectious disease. This is brought out by the following comparative table of the causes of blindness seen at provincial blind schools in 927 children in 1922, and 524 in 1944 (Sorsby, 1945b).

TABLE II.—Proportionate Incidence of the Main Causes of Blindness at Provincial Blind-Schools in 1922 and 1944

	Board of Education, 1922 (927 Cases)	Present Series 1944 (524 Cases)
Ophthalmia neonatorum	30.4	9.2
Purulent ophthalmia of later years	2.5	—
Phlyctenular ophthalmia	3.7	0.2
Interstitial keratitis	4.1	0.9
Iridocyclitis	2.5	0.8
Choroiditis	?	0.8
Syphilitic lesions	?	2.5
Optic atrophy	12.9	5.3
Congenital anomalies	—	—
Including myopia	37.2	67.6
Excluding myopia	30.8	55.0

This table shows a striking reduction in blindness from ophthalmia neonatorum and suggests a corresponding decline in blindness from congenital syphilis. As a corollary, blindness due to defects of congenital, hereditary, and developmental origin (in which myopia may be included) has assumed a proportionately increased significance. Two conclusions suggest themselves:

(1) The decline in the incidence of blindness in children is likely to come to an end within foreseeable time, in view of the fact that already some 65% of all blindness in children is due to defects of congenital or congenitally determined origin, and such defects are not readily amenable to treatment. It is therefore likely that blindness in children 5-16 years old will decline from its present rate of about 20 per 100,000 to about 12-14 per 100,000, but will remain at that level until more is known of congenital and congenitally determined disease.

(2) No substantial decline of the blind population as a whole is to be expected so long as there is no fuller knowledge of cataract, glaucoma, myopia, and the senile degenerations of the fundus oculi. Such decline as may be expected from better facilities for treatment may well be balanced by the shift towards more people in the higher age groups of the population as a whole.

A century of effort in public health legislation, hospital administration, bacteriology, and pharmacology is reflected in the diminution of the incidence of blindness. The further operation of these forces is likely to reduce blindness still more but at an ever-diminishing rate. Substantial advances can only come with intensive studies of the nature of genetic disease and intra-uterine infections on the one hand, and of cataract, glaucoma, and senile degenerations on the other. These are not all exclusively ophthalmic problems, any more than is blindness from infectious processes. In ophthalmology, however, these problems in pathology have become formulated perhaps more clearly than in other specialties.

Scotland.—In Marshall and Seiler's study of 3,219 blind persons 113 were aged 0-15 years, and of these 37 were blind from defects of congenital, hereditary, and developmental origin and 3 from myopia. This is a considerably lower incidence than that noted for the provincial blind schools of England. Proportionately there was more blindness from infectious disease. For the higher age groups their findings are essentially parallel with those for London and Middlesex.

The Dominions.—In the absence of more definite data may be assumed that the problems of the prevention of blindness in the white population are similar to those established for the British Isles.

Africa.—The limited inquiry of Rosset-Berdez for South African natives suggests that one in every twenty Africans is blind. If this is true and applies to Africa as a whole, it is unbelievable that such a state of affairs is not largely remedied. Fuller information is an urgent first step.

India.—Such Indian blind statistics as are available give prominence to lesions like anterior staphyloma (39.7% in one series), leucoma, and corneal ulcer. Trachoma is known to be endemic in some parts of the country; smallpox is still a significant cause of blindness, while ophthalmia neonatorum and congenital syphilis are recognized as important causes of blindness in children. All this is reminiscent of England at

beginning of the last century. The control of blindness in India is thus largely a problem of the control of infectious disease. That this is not purely an issue of pathology and pharmacology is obvious enough from the history of public health in Western Europe and is grimly emphasized by the fact that keratomalacia—a nutritional deficiency disturbance—is ranked as first among the causes of blindness in children. The problem of blindness in India is not one of the elimination of a particular infectious disease such as trachoma or the acute ophthalmias. It has to be conceived in terms of standards of living, education facilities for treatment and adequate and well trained ophthalmic personnel. None the less there is much that can be done immediately both outside and as part of the long term plans—how much, can be seen more clearly from a consideration of the position in

Egypt and Palestine—Here the social problems are not dissimilar in their broad aspects from those seen in India but unlike in India two clearly defined infectious diseases are the main causes of blindness—the acute purulent ophthalmias and trachoma. Purulent ophthalmia the more significant cause is now easily treated by the sulphonamides and by penicillin. An immediate and striking reduction of blindness in Egypt, Palestine (and indeed throughout the whole of the Near and Middle East) and perhaps India could be brought about by the organization of relatively simple treatment stations and possibly mobile units, with adequate supplies of the new chemotherapeutic and antibiotic agents. Trachoma, too could be considerably reduced by such stations, for the beneficial effect of sulphonamide therapy in trachoma is no longer open to doubt; moreover there are indications that penicillin may also be highly effective. The creation of such treatment stations will in any case have to be undertaken in any long-term programme but a sense of urgency has now been supplied by the availability of the new therapeutic agents for each day that such treatment is not available to the millions of Africa and Asia adds many blind to the roll of the avoidably blinded.

Summary

1 The number of blind in the British Isles is not less than 90 000 and is likely to exceed 100 000. In the white population of the Dominions it is between 40 000 and 50 000. In the native population of the British possessions in Africa, Asia, and Indonesia it is considerably more than 10 millions.

2 There has been a marked decline in the incidence of blindness in childhood in England and Wales during the past 21 years, but there is no evidence that there has been any substantial decrease in the older age groups. Before long the decline in the incidence of blindness in childhood will come to an end, as already about 65% of all blindness in children is due to congenital and genetic infections not readily amenable to treatment. With the rapid elimination of blindness due to infectious disease, intensive research in the problems of genetic disease, maternally transmitted infections, cataract, glaucoma and the pathology of senescence has become an immediate task if the incidence of blindness in England and Wales is to be reduced.

3 In the native populations of the British possessions the incidence of blindness could be reduced immediately and effectively by the organization of facilities for the intensive exploitation of the sulphonamides and penicillin in the treatment of the widely prevalent ocular infections.

OBSERVATIONS ON OEDEMA OCCURRING DURING THE COURSE OF MACROCYTIC ANAEMIA

BY

E. G. HOLMES, M.D., M.R.C.P.
Lieut. Col., R.A.M.C.

Tropical or nutritional macrocytic anaemia is described in the textbooks and Wells in India, Trowell in Africa and a number of other workers have investigated it. Unfortunately, service conditions render this literature inaccessible and in this account of certain features of the disease which seem of practical importance I may be treading on ground that has already been covered. Reference to previous work is omitted from necessity, not from negligence.

The textbooks describe the disease as an anaemia often severe of a macrocytic type occurring in India, Africa, the Balkans and southern United States among populations suffering from poor nutrition. It is often seen in pregnant women. It is accompanied by fever, diarrhoea, sore tongue, and sometimes oedema (which seems to have been referred to cardiac decompensation). Achlorhydria is said not to occur. Haemolytic and non haemolytic types of the condition are distinguished.

Discussion with fellow officers suggests that many cases of this kind occur in South East Asia Command, more commonly among Indian troops, less so among East Africans, occasionally among West Africans and hardly ever among British soldiers. It is proposed to discuss a series of 38 cases among East Africans, living stress on certain features.

Table I shows the frequency with which the signs and symptoms mentioned above were observed in this series. Anaemia of a more or less severe degree was noted in all (several patients had blood counts of less than one million red cells when they came under observation). It is not proposed to comment especially on the cytology which conformed to the textbook description. Macrocytosis was observed in all cases and normoblasts were seen on a number of occasions. The absence of an adequate centrifuge precluded determinations of mean corpuscular haemoglobin concentration or of other features requiring haematocrit readings. On several occasions the cells were reported to be macrocytic and hypochromic. Sternal puncture was done in several cases. It always revealed an actively normoblastic marrow. Sickling of the red cells was never observed nor was increased fragility, even in cases which were clearly of a haemolytic type. No neurological features of any kind were noted.

TABLE I

Total cases	38
Chills	12
Caustic HCl in the stomach	1
Absent	12
Present	10
Not determined	16
Diarrhoea	12
Normoblasts	12
Macrocytosis	12
Haemolysis and ascites	12

While gross anaemia can be missed only through negligent examination it will be obvious that the other signs and symptoms except the oedema and ascites (which will be discussed more fully) and the achlorhydria may be attributed to a number of complaints very common in South East Asia Command. Haemoglobin determinations alone are insufficient to exclude a moderate anaemia of this type. The only safe procedure is to count the red cells as well as to estimate the haemoglobin. At the least, a well prepared thin film should be examined by a reliable observer. In this hospital some cases were certainly missed before this point was appreciated.

Fever is usual in the more severe cases and may be mistaken for that of malaria or other illnesses. Diarrhoea may be attributed to dysentery or to infestation with worms or flagellates. Several cases at first labelled "non-specific diarrhoea" proved later to be macrocytic anaemia. Splenomegaly may be attributed to malaria or schistosomiasis, and indeed in the cases under consideration it was difficult to be sure whether the enlarged spleens observed were in truth connected with the

anaemia or with a legacy from earlier disease. Jaundice, when present, is more likely to suggest infective hepatitis than anaemia.

Prominence of one or more of these signs may lead to a wrong diagnosis unless the possibility of macrocytic anaemia is kept in mind as an underlying cause, and appropriate investigations made.

The occurrence of oedema and ascites merits special discussion. Fairley and Low (1939) attribute it to the cardiac insufficiency. It occurred in 12, or nearly one-third, of the present series of cases, in all but one, however, it did not appear until, as a result of treatment, the blood count had risen considerably. At this time other signs which could be attributed to cardiac decompensation were entirely absent.

Dietary deficiency is known to be a cause of macrocytic anaemia, and although an East African soldier's diet is probably better than that to which he is generally accustomed in civil life, it contains only 41 g. of first-class protein. The manufacture of haemoglobin involves the synthesis of protein as well as the manufacture of the iron-containing haem molecule. For every gramme of iron in haemoglobin there are some 800 g. of protein. If an individual with 6 litres of blood in his body is to raise his haemoglobin by 1 g. per 100 c.cm. of blood he must manufacture 60 g. of protein. It is not uncommon in these cases for the haemoglobin to fall as low as 6 g. per 100 c.cm., in which case to restore it to normal nearly half a kilogramme of protein

"heavy" nitrogen were introduced into the body by injection or by feeding, the "heavy" nitrogen atoms could be identified in the protein of all the body tissues, including plasma.

Once the osmotic pressure exerted by the plasma protein below a certain critical level fluid can no longer be held in capillaries, and oedema or serous effusions result. If a reduction of plasma proteins does in fact determine the occurrence of oedema and effusion in these cases it should be possible to demonstrate it, and observations were undertaken with this end in view.

After the work had been planned and started, a copy of *B.M.J.* for Jan. 13, 1945, became available. This contained a paper by Trevor Davies recording a case of oedema and recovery from anaemia. He found that the total serum protein when the oedema was fully developed, was 4.16%, the albumin 1.8%, and the A/G ratio 0.76/1. At this time the red cell count numbered 3,700,000. A month later, as a result of plasma transfusion and protein feeding, the total serum protein was 5.61% and the A/G ratio 1.5/1. The writer quotes a case of plasma transfusion in severe macrocytic anaemia (J. McD. Holmes, 1944)—not available here. He also quotes Heath and Taylor (1936) as stating that for a rise in the haemoglobin level 80 g. of protein must be retained.

The equipment necessary for plasma protein estimation was not provided in the laboratory of a field hospital, and

* This estimation was done at another hospital, and taken from the patient's notes.

will have to be forthcoming. Further, the protein moiety of haemoglobin is believed to belong to a class of proteins which are known to be particularly rich in diamino-acids, such as arginine and lysine, and, since there is evidence that these substances cannot be synthesized in the body, proteins which contain them must be eaten. Even so, it is possible that a good many molecules of food or body protein have to be broken down before the necessary constituents can be obtained for the manufacture of a molecule of haemoglobin. This may result, during the periods of blood regeneration, in a very heavy drain on the total protein resources, during which the plasma protein may become depleted.

It has been held that the plasma proteins do not form part of the general protein currency of the body. This can hardly be maintained in view of the work of Schoenheimer and his collaborators, who showed that if amino-acids containing

method used, based on that of Walther (1941), had partly been improvised. Details are given in the Appendix to this paper. All the determinations were made on sera, since plasma cells cannot be freed from cells without a centrifuge.

In the first instance a number of estimations of total serum protein were carried out. Though in several instances the total serum protein of cases with oedema was much diminished (e.g., the patient had a total serum protein of 4.9%, with gross oedema, on Dec. 24, 1944) the figures did not clearly establish the point at issue, but the figure for total serum protein may not be a sufficient criterion. The osmotic pressure of the serum depends upon the sum of the osmotic pressures of its albumin and globulin components (that exerted by fibrinogen is very small). The albumin is the smaller molecule and is said to exert about four times the osmotic pressure of the globulin. A serum in which the albumin is decreased and

the globulin normal or raised may therefore exert a lower osmotic pressure than a serum of equal or less total protein content but containing a higher proportion of albumin. Still the following figures as "normal": Total protein, 6.3-8.0%; albumin, 3.8-5.2%; globulin, 2.0-3.5%; A/G ratio, 1.45/1 to 2.2/1.

The total colloid osmotic pressure is said to lie between 20 and 30 mm. of mercury. Oedema is said to occur if the total protein falls below 5.5% or the albumin below 2.5%. It is clear from this that fractionation of the serum protein is required if the influence of the serum protein in determining the oedema is to be assessed.

Table II gives the results of a number of control determinations on sera of cases without anaemia or oedema. In Table III are given the corresponding figures for anaemic patients, some of whom were oedematous, and for one or two other cases with oedema and anaemia due to other causes.

It will be seen from Table III that Nos. 44131 and G/1419, though grossly anaemic and very ill, were free from oedema or ascites and had serum albumin levels well over 3.0%. No. 40866 on April 24, 1945, was grossly oedematous, and his total protein was very low, although his albumin was only just under 3% and his A/G ratio normal. A comparison of these three cases shows that the A/G ratio, taken alone, has no particular significance (see also No. 14404 in Table II, in which the A/G ratio is low because of increased globulin). No. N/22916 had moderate oedema and ascites on April 29. It was much worse on May 9, by May 30 it was improving, and it had disappeared by June 19. Two determinations on DN/22926 are included to illustrate a type of case in which oedema has long been accepted as being due to lowered serum protein, while G/3112, who had a little ascites, exemplifies yet another condition with a low albumin and a reversed A/G ratio.

The presence of oedema and ascites in these cases of anaemia has certainly given rise to errors in diagnosis. It often occurs at a stage when the anaemia is not impressive, and at which it may be missed altogether if reliance is placed on haemoglobin estimations alone. Two such cases were evacuated to this hospital with the diagnosis of hepatic cirrhosis, and in another vitamin B deficiency was suspected.

Aetiology and Complications

These are discussed together because I feel in a real difficulty of the "chicken and egg" variety. Certain conditions have been observed sometimes to accompany the anaemia, but whether they are also its cause is very difficult to determine. Table IV gives the conditions which were noted in this series.

TABLE IV.—Conditions Present

Ankylostomiasis	11*	Malaria	2*
Pulmonary complaints	9*	Serub typhus	1
Amoebic dysentery	3	Schistosomiasis	1
Bacillary dysentery	1	None	12

* One patient suffered from malaria, ankylostomiasis, and a mild attack of pneumonia.

It will be seen that 12 of the cases suffered apparently from uncomplicated anaemia. Ankylostome ova were found in the stools of 11. In spite of the prevalence of dysentery, in only 4 of these cases was its presence established either during or before the onset of the anaemia. We can find no evidence suggesting that the anaemia was caused by dysentery; the diarrhoea from which many of them suffered was a feature of the anaemia itself, and was not caused by a bowel infection. In only two cases was the presence of malaria parasites established. (This raises a difficulty because the majority of East African troops come from districts in which malaria is hyper-endemic, and one would expect a higher parasite rate. On the other hand, they were all on suppressive mepracine.) The proportion of respiratory complaints, varying from a mild bronchitis to frank pneumonia, was high. One patient was admitted with pneumonia and developed a macrocytic anaemia while in hospital.

Case DT/1574—On admission (21/12/44): Temperature 103°, pulse 120, respirations 32. Crepitations at both apices; no frank consolidation. Not clinically anaemic. Given sulphapyridine.

26/12/44: T. normal; chest clear. Sulphapyridine stopped.
27/12/44: Moderate fever; looks pale. Hb 54%, R.B.C. 2,750,000, C.I. 0.99. Slight anisocytosis. W.B.C. 10,975 (P. 67%, E. 12%, L. 16%, M. 5%).

30/12/44. T. 100°. Weak and listless. Weil-Felix and Widal, negative.

5/1/45: R.B.C. 1,830,000, Hb 38%, C.I. 1.05. Anisocytosis, poikilocytosis, polychromasia; myeloblasts and normoblasts present; no sickling.

8/1/45: Put on high protein diet and vegetable

21/1/45: Reticulocytes 5%.

23/1/45: Hb 82%, R.B.C. 4,630,000. Slight anisocytosis and poikilocytosis. W.B.C. 3,400.

26/1/45. Fractional test meal shows free HCl.

6/2/45. Hb 96%, R.B.C. 5,020,000, W.B.C. 4,160.

It is a pity that a red cell count was not done on admission. However, the blood counts of Dec. 27, 1944, and Jan. 5, 1945, illustrate the development of the anaemia. Large hypochromic red cells were present. The response of this case was particularly rapid. The impression gained from this and other cases is that though respiratory complaints do not cause the anaemia they may precipitate and exacerbate it.

That ankylostomiasis is potent in preventing recovery from anaemia was suggested by two cases in which ankylostomes were found and treatment was given soon after admission. After a time the anaemia failed to improve and further stool examination again revealed eggs. A second "worming" was followed by improvement in the blood count, and no more ova were seen. In fact, however, of the number of cases in which neither ankylostomiasis nor any other disease was found, it is difficult to make a case for a causal relationship between the anaemia and any of the infections commonly seen in this theatre.

Of the total cases 31 were evacuated from forward areas, and 7 were admitted from L. of C. units. It is likely enough that the hardships of a particularly strenuous campaign would precipitate the condition in men already predisposed. But these figures may be misleading. At the time when almost all the sick and wounded from the East African Forces came through this hospital, all but a handful of troops were in forward areas. Later, when the division was out of the line, the bulk of the sick were diverted to another evacuation route, and were not seen here.

No apology is made for labelling the above points. In this, as in other instances, prevention is more important than cure. There is danger lest loose statement to the effect that anaemia is "always" due to malaria or ankylostomiasis may blind us to more important underlying conditions such as inadequate diet. In any case it is thoroughly established that the anaemia or that caused by malaria and ankylostomiasis is characteristic of the microcytic type and therefore different from that described. To expect a man who has had a diet poor in iron and protein since he was weaned to maintain or replenish his haemoglobin in the face of hard campaigning conditions, without added infection, may be to expect him to make bricks without straw.

Treatment

Of the series one patient died from an intercurrent attack of cholera. Three were evacuated (when improving) because of pressure on hospital bed-space, and one was graded Category C on account of an old chronic synovitis of the knee. All the remainder have been returned to duty in Category A except five who are still under treatment. Some of those discharged still had achlorhydria, though three, originally achlorhydric, were found to secrete HCl when reviewed after return from the convalescent depot. Those with persistent achlorhydria all had normal blood counts, had put on weight, made no complaints of dyspepsia, and seemed so well that, rightly or wrongly, the finding was ignored and they were returned to duty. It seems therefore, that the treatment given may be regarded as satisfactory in a long-term sense. But it has proved very slow. The average duration of treatment (including time at the convalescent depot) was 105 days: the longest 175 days, the shortest 58.

It is stated (Fairley and Low, 1939) that the condition responds to marmite, to liver, to liver extract by mouth equivalent to 1 lb. of liver a day, and to parenteral administration of liver extract. In the haemolytic type the doses of these substances may have to be very large. These authors say that before, the introduction of liver therapy the mortality rate was around 40%. Moore, Vilter, Minnich, and Spies (1944), working on a series of cases in America, found that these

responded to parenteral liver and to beef muscle by mouth, and further showed that the following substances were without effect: niacin, thiamine, riboflavin, calcium pantothenate, pyridoxine, inositol, para-aminobenzoic acid, and choline.

In the present series the supply of therapeutic substances was too irregular to allow of more than a "shot-gun" regime of treatment. The diet contained about 4,000 calories. There were approximately 165 g. of protein, of which 38 g. were contained in meat (muscle), 22 g. in liver (when available), 31 g. in milk (including cheese), and 12 g. in eggs, giving 103 g. of first-class protein. (Anyone familiar with the supply position of the forward hospitals will realize that not infrequently one or more of these items were not available.) In addition, each patient received 2 to 4 oz. of vegemite (marmite substitute) and 9 multivite tablets per day. Each received an iron preparation twice daily, and for a time 2 oz. of dried yeast. For a considerable period no liver extract for injection was available, and that eventually supplied was of Indian manufacture and doubtful potency. A quantity of liver extract for oral administration was available for some time.

In all, eight patients received liver by injection. In two only was a reticulocyte response observed. Two patients showed a reticulocyte response on vegemite. Eight patients had one or more blood transfusions because of their precarious condition. Three of these were previously given at other hospitals. More would have been given at this hospital but for the difficulty of persuading East Africans to act as blood donors. However, several patients whose condition seemed very precarious, but from whom blood had to be withheld for the reason mentioned, made a good though slow recovery without it.

Treatment of Oedema and Ascites

Five of the oedematous patients received intravenous infusions of reconstituted serum. This treatment was followed by a diuresis, and in three cases the oedema and ascites began to clear up a few days later. In the other two it appeared to have little effect. It is felt that this line of treatment should perhaps have been followed more vigorously. The difficulty was, first, that the amount of serum available was limited, and a good supply had to be conserved for surgical emergencies; secondly, that the giving of serum was usually followed by a sharp rise of temperature and a good deal of malaise and discomfort. The water used to dissolve it had been bottled for some time, and one would have felt happier in preparing fresh ammonia-free water; no glass still was, however, available. A 100 c.c. of serum will contain about 40 g. of protein, of which about 22 g. will be albumin, this would raise the serum albumin to about 0.5.

In the presence of a large effusion the question of paracentesis arises. The fluid contains protein which is for the time being out of circulation, though if the effusion is naturally absorbed it will presumably become "current coin" again. If, however, part of it is removed by paracentesis, and is replaced again (as so often happens) by further effusion, protein will be irrevocably lost to the body. As an example, on May 28, 1945, 2,570 c.c. — a very small part of a huge ascites — was removed from the abdomen of No. 40866. This contained 93 g. of protein, of which 40 g. was albumin. The removal of this fluid made little difference to his comfort, and in a few days he was as distended as before. Subsequently (June 19) the oedema and ascites began to diminish, and had all disappeared in a few days. Earlier, N/22916 had had 3,640 c.c. withdrawn at the cost of 32 g. of protein (which in this case was all globulin). He "filled up" again very quickly. Subsequently the whole effusion was absorbed. It is thought that, unless really serious embarrassment is being caused, effusions in these cases are better left alone.

Conclusion

In writing this imperfect account I have made use of some data — e.g., the first figure in Table III — contained in the documents of patients transferred from other hospitals, and, in certain cases, of the notes of other M.O.s (particularly those of Capt. R. A. Shanks, R.A.M.C., of this hospital). I am greatly indebted to Major A. B. Raper and his staff, especially S Sgt M Fitch, R.A.M.C., for all the haematological examinations, for routine pathological examinations, and for facilities for carrying out the serum protein determinations.

Summary

A brief account is given of 38 cases of tropical (or nutritional) macrocytic anaemia among East African troops. The aetiology of the condition in S.E.A.C. is discussed.

Particular attention is paid to the occurrence of oedema and effusions. They were observed in nearly 30% of cases, and appear to coincide with the regeneration of red cells rather than with the acute stage of the disease.

A number of estimations of serum protein have been performed. Their significance is discussed.

APPENDIX

The method used for serum protein determination was based on that of Walther (1941) for total serum of plasma protein. 0.02 c.c. of serum of plasma (measured by means of a haemoglobinometer pipette) is digested with 0.25 c.c. of sulphuric acid and 0.5 c.c. of saturated potassium persulphate. The digested mixture is made up to 40 c.c., nesslerized directly, and compared in a colorimeter against standard ammonium sulphate solution. In the original method a standard correction is applied for non-protein nitrogen, since it is estimated along with the protein nitrogen. In this work boiling-tubes, a spirit lamp, sulphuric acid, persulphate, and Nessler's solution were available, and the laboratory still fortunately yielded ammonia-free water. There was, however, no colorimeter. Fortunately, the commanding officer had brought with him a Lovibond tintometer, and the 0-100 mg. blood-urea disk. These disks are, of course, made for use under the precise conditions laid down by the makers and with Nessler's solution made to a certain formula. These conditions could not be fulfilled, so urea, dried in an improvised desiccator, was weighed out, dissolved, and the solution containing known amounts of urea treated exactly as the serum would be, and used to standardize the disk in terms of mg. of nitrogen per c.c.m.

The serum total nitrogen was then determined as described by Walther. After digestion the volume was made up to 25 c.c.m. and the nitrogen estimated in the comparator. Dilution, which was achieved by mixing the digest with ammonia-free water in the comparator tube, keeping the final volume 5 c.c.m., was carried out if required.

Non-protein nitrogen was estimated by mixing 2 c.c.m. of serum, 2 c.c.m. of distilled water, and 2 c.c.m. of 10% trichloroacetic acid, filtering, and digesting 1 c.c.m. of the filtrate with 0.1 c.c.m. of sulphuric acid and 0.2 c.c.m. of persulphate, and making the final volume 10 c.c.m. Nesslerization and comparison were carried out as described above. This is not very satisfactory: the colour comparison is often hindered by cloudiness in the tube, due probably to the precipitation of inorganic phosphate. If, on the other hand, this is avoided by greater dilution, the colours (with normal N.P.N. levels) become too pale to be read. With this procedure, of course, the amount of filtrate digested is equivalent to 1/3 c.c.m. of serum, instead of 1/50, which is used in the method for total protein. Fortunately, the protein equivalent of the N.P.N. is small, and the inaccuracy involved is not material.

It is worth noting that if the N.P.N. is high the difficulties mentioned disappear, since greater dilution can be used, and the method is then a quick and accurate one (e.g., Table III, No. DN/22926).

The fractionation of albumin and globulin was carried out on the usual principles: 0.2 c.c.m. of serum was mixed with 6 c.c.m. of 22% sodium sulphate (which was stored in the incubator) and the mixture allowed to stand at 37° C. No filter paper fine enough to filter off the precipitate was available, but by careful pipetting sufficient clear supernatant fluid could be obtained to carry out protein determinations, 1 c.c.m. of fluid (equivalent to 1/31 c.c.m. of serum) being digested as before. The blank tube contained appropriate amounts of sodium sulphate, sulphuric acid, and potassium persulphate. The result represented albumin nitrogen + N.P.N. The albumin was calculated from this and the globulin obtained from the figure for total protein by difference. All determinations were made in duplicate. Unless the duplicates were in good agreement they were repeated.

It will be appreciated that these methods were used from necessity not from choice. The employment of so little as 0.02 c.c.m. of serum implies an enormous dilution factor and a corresponding exaggeration of random errors. Distillation after digestion is always preferable to direct nesslerization, because of the presence of interfering substances. The lack of a colorimeter was a very severe handicap.

SULPHAEMOGLOBINAEMIA DUE TO ANILINE DERIVATIVES

BY

S. LAZARUS, M.D., M.R.C.P., F.R.F.P.S.

Dispensary Physician, Western Infirmary, Glasgow

The continued use of aniline compounds may produce a marked and persistent cyanosis due to the formation of sulphaemoglobin in the red blood corpuscles. Attention has been directed in recent years to the frequency with which sulphonamide therapy is associated with sulphaemoglobinæmia, but the power of the humbler aniline antipyretics in this direction does not appear to be so well appreciated. Snapper (1925) described two cases of sulphaemoglobinæmia which were due to the continued use of aniline antipyretics. Similar cases have been described by Harrop and Waterfield (1930), Healy (1933) and Morgan and Anderson (1940) among others.

The toxicity of the different members of the aniline antipyretic group varies. The relative toxicity of acetanilide is high, and most of the reported cases of sulphaemoglobinæmia precipitated by aniline antipyretics have been due to that drug. Addiction to it has been observed and this danger has been emphasized by a number of observers. Acetanilide is now included in Part I of the Poisons List (1937) is not easily available to the public and hence widespread abuse of it is not to be expected.

Phenacetin presents a quite different problem. It is a component of numerous proprietary headache powders and can be obtained without difficulty. Its chemical structure is similar to that of acetanilide, it is less toxic, however, and cases of chronic poisoning by phenacetin are therefore seldom encountered. In large doses it can, as might be expected, produce poisoning, with effects, including sulphaemoglobinæmia, very much like those seen with acetanilide. Snappers (1925) two cases of sulphaemoglobinæmia were due to chronic poisoning with phenacetin, and Coxon and Crawford (1940) have reported another. Two cases of sulphaemoglobinæmia have been seen recently, and are described here.

Case I

On April 6, 1943, a housewife aged 42 was admitted to hospital on account of severe headache, weakness, and cyanosis. She had been subject to attacks of severe headache since childhood. These attacks occurred at least once a week and each lasted one to two days. Since the menopause in 1941 the severity and duration of the headaches had increased. The pain began in the crown of the head and then spread to one or other side. The patient could not account for the headaches. She read avidly without ill effect, and was free of nausea and photophobia during the attacks. She shunned company and crowded places, as she feared that an attack might be precipitated in these circumstances. In 1930 she received numerous injections of morphine to ease the headaches. Eighteen months before admission she had noted that her lips were blue, and she stated that her skin had been blue for about a year. This blueness was more pronounced during attacks of headache, and the patient's relatives had remarked on the blue colour of her face. She had taken many brands of analgesic powders for her headaches but two years before admission she resorted to a proprietary tablet (phenico) which contains approximately 3.6 gr. of acetylsalicylic acid and 2.1 gr. of phenacetin. She took between 4 and 10 tablets daily, according to the severity of the headache. During an attack of pain she had had as many as 30 tablets in a day (=63 gr. of phenacetin).

Her husband stated that in the last attack, which persisted for four days before admission, his wife had taken over 100 tablets. He said that the patient had become very irritable and depressed during the past few months. She was confused when the headaches were severe and kept swallowing tablets without regard to their number. During the past year she had been given 41 gr. of ferrous sulphate daily and monthly injections of anaheimin, presumably to improve her general condition.

On admission the patient was greatly distressed with headache but not confused. She was thin and poorly nourished. There was no dyspnoea, but cyanosis was very marked. The skin was a slate-grey colour, which was especially noticeable in the lips, ears, nose and beds of the nails. The temperature was 99° F, the pulse rate 100, and the respiratory rate 20 a minute. The pulse was regular and of good volume, the arterial wall was not palpable. The area of cardiac dullness was not increased and the heart sounds were well heard. A systolic murmur audible at the mitral area was not conducted. The chest was symmetrical and moved equally on both sides. Further examination did not reveal any abnormality of the

lunes. There was no evidence of any mediastinal abnormality. The abdomen was tense, but moved freely with respiration. The liver and spleen were not palpable. Examination of the retinas was not revealing any abnormality. The optic fundi were normal. The urine was free of albumin, sugar, and blood but showed the "diacetic acid fallacy" with ferric chloride solution.

Blood examination showed Hb, 105% (Sahli); red cells, 4,500,000 per cmm.; white cells, 4,200 per cmm. The blood films were normal. The venous blood was darker than normal and remained so despite shaking in air. On spectroscopic examination of mixed blood an absorption band was seen in the red portion (612-620 mμ) of the spectrum. This band was not affected by the addition of potassium cyanide solution and was presumed to be due to sulphaemoglobin. It was visible in a 1 in 100 dilution of blood in water two days after admission (April 8). No specific treatment was given. The headaches were considered to be psychogenic in type.

Progress.—The acute headache passed off after three days, but the cyanosis remained. Analgesics were withheld and so far as known the patient did not have a secret supply. Despite this it was 16 days before there was any obvious diminution in the cyanosis. Three weeks after admission the cyanosis had lessened considerably, but the sulphaemoglobin absorption band was still present in a 1 in 18 dilution of venous blood. The patient was discharged after four weeks.

Six weeks after admission (May 21) the cyanosis had almost disappeared although the sulphaemoglobin band was still detectable in a 1 in 12 dilution of the blood. Blood examination showed Hb 70% (Sahli); red cells, 4,800,000; white cells, 6,000 per cmm. On June 11—i.e. just over eight weeks after withdrawal of the tablets—spectroscopic examination of the blood failed to reveal a sulphaemoglobin band. The general skin cyanosis had gone but the lips were still dusky. Reviewing this case, we may conclude that the regular ingestion of phenacetin (8-20 gr. daily) over a period of two years had led to the formation of sulphaemoglobin in the blood.

Case II

A clerk aged 57 was seen as an out-patient on July 10, 1944. He had had severe pain in the left shoulder during the previous three weeks. The onset of the pain had been sudden and some improvement had occurred with local counter-irritant measures and analgesic powders. There was no dyspnoea.

The patient was a cheerful well built man. Marked cyanosis of blue-grey colour was seen in the lips, face, ears, and especially in the nail beds. Systemic examination did not show any further abnormality. In particular there was no evidence of any upset of the respiratory and cardiovascular systems. Blood films were normal. Hb 95% (Sahli); red cells, 4,250,000 per cmm.; white cells, 7,800 per cmm. The urine appeared to be normal on chemical examination. Rheumatic myalgia of the left deltoid muscle was also responsible for the pain, it responded to massage.

Analgesic powders prescribed by the patient's doctor contained 0.9 gr. of phenacetin and 5 gr. of acetanilide. Twelve powders were taken each week. Thus when first seen he had had a total of 24 gr. of phenacetin and 120 gr. of acetanilide in two weeks.

On being questioned he stated that the blue colour of his face had been noted by his relatives for a week and that it had caused them some concern as they feared it was due to "heart trouble". The venous blood was darker than normal, having a chocolate tinge. An absorption band in the red was found on spectroscopic examination. This band was not affected by potassium cyanide solution and it was thought to be due to sulphaemoglobin. The band was only detected in a 1 in 65 dilution of the blood.

More powders were given and the patient made an unremarkable recovery. As is usual in sulphaemoglobinæmia, the cyanosis disappeared slowly. Thus one week later (July 17) cyanosis was still present and the sulphaemoglobin band was detected spectroscopically in a 1 in 70 dilution of venous blood. Two weeks later (July 24) the cyanosis was definitely less marked. The patient resumed his employment and did not return for further observation.

But acetanilide and phenacetin had been taken in this case and he may have contributed to the formation of the sulphaemoglobin. However, acetanilide, because of its greater toxicity, may be held largely responsible. No treatment of the cyanosis was given apart from withdrawal of the drugs. Long and Spriggs (1918) noted that inhalations of carbon dioxide and oxygen improved their cases of sulphaemoglobinæmia. Healy (1933) gave carbon dioxide and oxygen inhalations, together with a high fat diet and ammonium chloride, to two cases of sulphaemoglobinæmia and reported that the cyanosis disappeared within a week.

Discussion

Apart from the different drugs involved these two cases of sulphaemoglobinæmia may be taken as examples of two clinical types in which cyanosis is due to aniline antipyretics can occur. Case I is an example of the entity called "enterogenous"

cyanosis." The salient features here are psychological instability, weakness, chronic headache, and cyanosis without associated dyspnoea, occurring almost exclusively in women. While it is just possible that some of these cases may be idiopathic, it is now recognized that the majority are due to the ingestion of aniline antipyretics. The self-administration of drugs is often denied by these patients, and careful search may be necessary to find the actual cause of the sulphaemoglobinaemia. Case I suffered a relapse some months after dismissal. This patient was admitted to another hospital and a normal ventricular system was demonstrated by cisternal encephalography. She was then examined by a psychologist, who reported that the symptoms were psychological in origin. Case II presents many different features. Here the drugs were taken to obtain relief from pain caused by an organic condition. The pain of rheumatoid arthritis, as in the case reported by Coxon and Crawford (1940), or of rheumatic myalgia as in the case here described, may be the prime factor. Both sexes may be affected, psychological instability is not present, and the tendency to habit formation is not marked.

The mode of formation of sulphaemoglobin is the same whether it is produced by aniline itself or one of its derivatives. According to Snapper (1925), the circulating haemoglobin is sensitized by aniline derivatives and can thus unite with traces of sulphide absorbed from the intestine. Snapper induced sulphaemoglobinaemia in men by administering aniline compounds and sulphur. Outside the body, however, aniline and its related compounds have no effect on haemoglobin. It appears that aniline compounds are oxidized to the corresponding phenyl-hydroxyl amines and *p*-aminophenols in the blood stream and that these substances affect haemoglobin. Gley (1937) and Morgan and Anderson (1940) have demonstrated that both these substances, when added to blood, lead to the rapid formation of sulphaemoglobin if a trace of sulphide be present, and to methaemoglobin if sulphide be absent. Methaemoglobin can be produced only with difficulty by giving aniline antipyretics alone (Harrop and Waterfield, 1930). Further, methaemoglobin is highly unstable in the blood stream, being rapidly converted to haemoglobin (Stadie, 1921), and large quantities are required to produce cyanosis. Such cyanosis lifts within 24 to 48 hours after withdrawal of the drug, and is more likely to appear in acute than in chronic poisoning.

Finally, there is some evidence in favour of the view that coloured oxidation products of *p*-aminophenol are present in the blood after the ingestion of aniline compounds and that these are partly responsible for the cyanosis. Leslie (1939) described a case of acute acetanilide poisoning in which marked cyanosis was not associated with any change in the blood pigment and was considered to be due to the presence of some coloured derivative of acetanilide in the blood. Lundsteen, Meulengracht, and Rischel (1938) described 11 cases of chronic acetanilide poisoning with cyanosis, and were able to demonstrate a chocolate-coloured derivative of *p*-aminophenol in the blood of one of their cases which was specially investigated. It is difficult, at present, to assess the importance of this coloured *p*-aminophenol derivative in the production of cyanosis. In the majority of cases of chronic poisoning with aniline antipyretics, including the two described here, the cyanosis has been adequately, if not completely, accounted for by the presence of sulphaemoglobin in the blood.

Summary

The clinical and laboratory findings in two cases of sulphaemoglobinaemia due to aniline antipyretics are described. The method of formation of the abnormal pigment and other factors which may contribute to the cyanosis are discussed.

I wish to express my indebtedness to Dr. John Gracie for permission to investigate cases under his care, and to Drs. S. V. Telfer and G. H. Bell for their advice and help.

THE CHILD WITH FREQUENT COLDS

BY

D. H. IRWIN, M.B., Ch.B.

Medical Superintendent

AND

E. FRANKEL, M.D., M.R.C.P.

Physician

Essex County Hospital, Wanstead

In this article are given the results of a comprehensive investigation of 100 school-children suffering from frequent colds. At the invitation of the County Medical Officer, the children were referred by the school medical inspectors in the area of South-West Essex to a special clinic established at the hospital for the purpose of investigating this prevalent condition. The children were mostly drawn from middle-class and artisan families. The main part of the investigation consisted of clinical, x-ray, and laboratory examinations, and note was also taken of the environment and development of the children. While our chief purpose was to establish the clinical characteristics of the child with frequent colds, we also considered the problem of which department in a hospital should be responsible for their examination and should advise on their treatment.

It was inevitable that a number of children suffering from asthma and hay-fever should be referred to such a clinic. If these are excluded the history of the disorder is a typical one. The children usually began to suffer from frequent colds when they started attendance at school. They complained at first of blockage of the nasal passages followed by a mucous discharge which after a few days became muco-purulent. Often there was also a mild upper respiratory infection, with slight cough but little sputum. The general constitutional disturbances always found in an adult suffering from coryza were absent. The cold will last about two weeks, and then the child may be free for a few weeks until the next attack. This cycle will continue right through the winter and may often be present during the summer months, though the colds are usually less severe in the warm weather. In a small number of cases there was continuous muco-purulent nasal discharge between the attacks. Many of these children had had these frequent colds for as long as three years. While the children remain fairly well in spite of these frequent attacks, both the parents and the education authorities show concern at the amount of schooling lost. Some parents are also anxious lest the frequency of the attacks denotes some constitutional deficiency or even serious organic disease—e.g., tuberculosis.

We have examined 130 children, the findings in the first 100 of which are given below. There were 59 boys and 41 girls in this series. Four children were between the ages of 1 and 5, 69 between 6 and 10, and 27 between 11 and 15 years.

History

Their birth weights were all within normal limits, and they all developed normally from birth, reaching the usual milestones at the expected ages; 88 had been breast-fed and 12 bottle-fed; and 95 were given cod-liver oil and orange juice or other additional vitamins to supplement a normal diet. Only 2 children were in the habit of going to bed late. We analysed this series with regard to previous infectious diseases and found that 84 had had measles, 59 whooping-cough, 3 diphtheria, 59 bronchitis, 23 tonsillitis, and 14 otitis media. The majority of them had been vaccinated and immunized against diphtheria. No definite relation was found between any of these infectious diseases and the onset of colds. In 33 cases the mothers complained that their children snored at night and were mouth-breathers. Twenty-one children had had their tonsils and adenoids removed before being seen by us, mainly for the relief of frequent colds, and of these 18 were not improved. A near relative of 26 children had suffered from tuberculosis and of 22 from an allergic condition.

Clinical Examination

These children all showed normal weights and heights for their age and sex, and appeared to be well developed and of normal intelligence, with the exception of 3 who were slightly

backward. None showed evidence of rickets. Their temperatures, pulse, and respiration rates were normal. Eight had carious teeth. Tonsillar enlargement of varying degrees was present in 39 and the adenoids were prominent in 27. In no case was there complete nasal obstruction, and the adenoid facies was rare. We specially observed the shape of the thorax of these children, and found that in 17 it was definitely barrel-shaped, in 5 alar, and normal in 78. In no case was serious lung disease found, but 8 showed a few scattered rhonchi and occasional rales. The heart, abdomen, and central nervous system were normal in all cases. No serious organic disease was therefore found on clinical examination.

Investigations

A number of laboratory tests were done on every child. The haemoglobin in 2 cases was between 60 and 70%, in 6 between 71 and 80%, in 45 between 81 and 90%, in 16 between 91 and 95%, and in 31 over 95%. The white count was between 6,000 and 10,000, and in no case was there a leucocytosis. The differential count showed some interesting features. Only 3 had increased eosinophils, but there were more than 40% of lymphocytes in 53 of the patients, showing a relative lymphocytosis. The urine was normal in every child. B.S.R. (Westergren) was done in one-third of the children, and was within normal limits. Twelve children had a positive Mantoux (1:1000), and 5 of these had positive family histories. None of them showed any other evidence of tuberculous infection, and there was no relation between the positive Mantoux reaction and anaemia or frequent colds. X-ray examination of their chests showed mild catarrhal changes in 49, particularly in the right lower zone, and also slight increase in the hilar markings. Skiagrams of their sinuses showed definite opacities in one or both maxillary antra in 51, and this was the most common abnormality found in the investigations done on these children. The radiographic appearances were thought to be due to mucosal swelling and thickening in the majority of cases, and only 3 showed opacities thought to be caused by actual pus in the sinuses.

Each child was also tested for allergic skin sensitivity to the common air-borne inhalants by the intradermal method, and to the pollens and the main food groups by the scratch test. In all, 14 groups covering 60 substances were used. No food sensitivity was discovered in any child. Eleven children showed positive reactions; 4 of these were cases of hay-fever and had marked sensitivity to pollens, and 5 were cases of bronchial asthma showing marked sensitivity to air-borne inhalants, those most frequently incriminated being house dust, feathers, horse dander, cat, dog, cow, wool, and furs, in that order. The remaining 2 cases gave positive skin reactions to air-borne inhalants, but the symptoms for which they had been referred were not regarded as allergic. The skin-testing was done independently of the history-taking and clinical examination, and therefore any bias in its interpretation can be excluded. It is interesting that in every case where an allergic factor was diagnosed it was confirmed by skin tests. At the clinic at this hospital for children suffering from respiratory allergy, in which skin sensitivity tests are done, 80% show positive reactions. This is in marked contrast to the present series, only 11% of which had positive skin reactions to the common air-borne inhalants. Two other features distinguishing the two groups are the absence of radiological abnormality of the nasal air sinuses in the allergic group and the low incidence of eosinophilia in the present series as opposed to the allergic.

The cervical, axillary, and inguinal groups of glands were carefully examined, and enlargement of the cervical chain of glands was noted in 30 cases. This was usually found in patients with enlarged septal tonsils. In addition, however, many children showed enlargement, sometimes to a considerable extent, of the other groups of lymph glands. This generalized glandular enlargement seems to be common in children who have an active septic or tuberculous focus, though often no obvious cause can be found. Twenty children with adenopathy had several additional investigations done to see whether further light could be thrown on this clinical problem—namely, the Paul-Bunnell test, Wassermann reaction, and biopsy of a small gland in 6 cases. All these tests proved negative, and the results of the routine investigations in no way differed from those

obtained in children with no generalized glandular enlargement. The glands studied histologically showed activity only in the germinal centres, and the general structure of the gland was quite normal.

No bacteriological examination of the muco-purulent nasal discharge was made. Many workers have investigated its flora and the results are well known.

Conclusions

From these investigations we learn that the child with frequent colds is of normal development, build, and intelligence, and does not suffer from any other organic disease. Though minor degrees of anaemia occur, the children cannot be regarded as physically defective. The onset of the attacks at the beginning of school suggests that the continuous contact with infection is an important aetiological factor. No definite relation was found between the colds and developmental abnormalities, upbringing, previous illnesses, or contact with tuberculous infection. No conclusion can be drawn from the lack of improvement after tonsillectomy, as naturally the children who improved after this operation would not be sent to the clinic; but we believe that in the absence of other indications, such as infection of the tonsils or nasal obstruction due to adenoids, surgical removal of the tonsils and adenoids will be relatively ineffective as a measure designed to prevent frequent colds. No allergic aetiological factor could be established. Investigation of the blood, the Mantoux test, and special investigations with regard to glandular enlargement, though of general interest, did not throw any light on this condition. These frequent colds are due to inflammatory reactions of the mucous membrane lining the nasal passages and air sinuses, and give rise to few general constitutional disturbances in children. A filterable air-borne virus seems to be responsible, aided by other organisms such as the pneumococcus, *Str. viridans* and *haemophilus*, *staphylococcus*, *Micrococcus catarrhalis*, or *Haemophilus influenzae*, which set up secondary infection. Repeated colds may cause nasal obstruction, and there may be arrest of nasal development and failure of muscular control over nasal respiration. These factors predispose the child to further infection.

We think that the treatment of this condition is entirely a problem for the ear-nose-and-throat surgeon, who should keep these children under supervision in a special clinic where they can receive conservative and operative treatment. A general medical or surgical, paediatric, or allergic clinic should not have to deal with these children, as, apart from the local conditions affecting the nasal passages, sinuses, and throat, no other abnormality could be discovered.

We wish to acknowledge our indebtedness to the County Medical Officer, Dr. W. A. Bullough, for his interest and co-operation in the investigation, and for permission to publish the results.

Dr. Douglas Lothian, resident medical superintendent of the Down Mental Hospital, Downpatrick, in his report for 1944 records that 39 patients were treated by the electro-convulsive method during the year, and 9 of them were discharged recovered, 3 being cases of dementia praecox and 6 suffering from depression. Two other cases of depression made such considerable improvement as to warrant the expectation that they would soon be discharged, as did 1 case of dementia praecox. Three cases of dementia praecox made an apparent recovery, but relapsed later; 2 cases made some improvement, but relapsed completely later. Forty-seven patients recovered without electro-convulsive therapy, but with psychotherapy and occupational therapy; these included 18 cases of dementia praecox, 16 depressions, 7 anxiety neuroses, 5 manias, and 1 paraphrenia. The other recoveries included a case of general paralysis of the insane treated by trypanamide and bismuth, 2 cases of arteriosclerotic confusion cleared up by careful attention to living habits, 1 case of uraemic confusion, and 2 cases of mental disorder resulting from alcoholism.

MASS MINIATURE RADIOGRAPHY OF FACTORY GROUPS IN MIDDLESEX

BY

W. POINTON DICK, M.R.C.S., L.R.C.P.

Physician to the M.C.C. Mass X-ray Unit

The Middlesex County Council Mass Radiography Unit took x-ray films of its first volunteer on Oct. 11, 1943, and to July, 1945, had examined over 70,000 persons, their ages ranging from 12 to 76 years. This report is confined to a survey of the work of the unit during the year 1944, with the exception of the age groupings of examinees and significant lesions, which are for the period Oct., 1943, to June, 1944. During 1944 ten factories were visited, their population ranging from 1,050 to 4,608. Neighbouring factories were invited to attend at most of these centres, so that the actual number of examinees varied between 706 and 9,640. Using the present set-up and the routine to be described below, it has been found to be uneconomic, from the point of view of time, to visit groups of fewer than 3,000. The response varied between 73 and 93% for inside groups, but fell to as low as 36% for some of the visiting factories. This was readily accounted for by the extra loss of working time when any considerable journey had to be made. The average period away from the work for an "inside" examinee was 15 minutes, and the unit has received letters from several firms stating that there was no appreciable loss in production time during its visit to their factory.

In a normal working week miniature films are taken on Monday, Tuesday, and Wednesday, and large films on Thursday. Friday is devoted to viewing miniatures, reporting on large films, and general clerical work. An average of 450 to 500 miniature films are taken daily, and as 500 is the maximum that can be satisfactorily viewed at any one sitting it is necessary to hold three viewing sessions weekly. During the first week of a visit there are four full days for miniatures, making a weekly total of 1,800 to 2,000, and the viewing sessions are correspondingly increased.

On Friday is completed the list of those persons required to attend for large films on the following Thursday. At one time it was the practice to send out the recall letters to their home addresses. In order to be sure of their receiving them in time it was necessary to post the letters a few days before the examinees were required to attend. We found that this period of waiting caused considerable anxiety and the development of a few symptoms. To obviate this, examinees are now notified, where possible, by a note handed to them at their work an hour or so before their large film is due to be taken. Usually all persons who have a large film have a medical interview, including a discussion on their wet film, shortly after it is taken. In this way, by the time they return home from their work the whole procedure is completed.

Analysis of Results

The total number of examinees during 1944 was 34,227, comprising 19,609 males and 14,618 females. It has been impossible to date to set these out in age groups, but this has been done for the 20,982 persons examined by the unit during the period Oct., 1943, to June, 1944, and these are shown in Table I.

TABLE I—Age Groups of Examinees

Age:	14-24	25-34	35-44	45-54	55+	Total All Ages
M ..	1,758* (14.6%)	3,652 (30.4%)	4,222 (35.5%)	1,610 (13.4%)	722 (6.0%)	12,010
F ..	3,680 (41.0%)	2,711 (30.2%)	1,718 (19.1%)	695 (7.7%)	168 (1.9%)	8,972

* It may be noted in regard to the small number in this group that in a paper by Trail *et al.* (1944) reporting a survey in the Royal Air Force 70% of the male examinees were in the 17-24 age group and that the incidence of active pulmonary tuberculosis among them was 0.3%.

Refusals.—It was possible to analyse the refusals by 682 persons from two factories with a total available population of 5,930. The result is given in Table II.

TABLE II.—Analysis of Refusals by 682 Persons

Age	Men		Women	
	Available	Refusals	Available	Refusals
14-34 ..	1,177	67 (5.7%)	2,167	165 (7.6%)
35+ ..	1,469	260 (17.7%)	1,117	190 (17.0%)

A further factory (Factory A of the Medical Research Council Report on Mass Radiography of Civilians) has been visited at yearly intervals, first by the M.R.C. and subsequently by this unit. It is of interest that out of 148 persons at this factory who refused in 1943 but who were x-rayed in 1944, and a further 214 who while refusing in 1944 attended for examination in 1945, there was not one who showed any evidence of pulmonary tuberculosis.

There were 1,909 examinees recalled for a large film in 1944 giving a recall figure of 5.6%. Of these, 50—that is, 2.6% of those recalled—did not attend for their large film. As would be expected, the number of defaulters was always higher in the outside groups, averaging 3.7%, compared with 1.6% for the main factories. There were a further 36 who, having had a large film and on interview been recommended to attend a chest clinic, failed to do so. Of those who attended a chest clinic 1.5% were reported as requiring no further action.

Abnormalities Found

The abnormalities discovered among the 34,227 persons examined by the unit during 1944 are listed below. They are divided into tuberculous and non-tuberculous groupings. Cardiovascular lesions predominated in the latter, and it is of considerable interest that the great majority of these patients were already aware of their disability.

A. Non-tuberculous Pathological Conditions

Cardiovascular	157 (0.5%)
Congenital 12; acquired 145 (86% already knew of their condition)	
Tumours	15
Bronchiectasis	31
Lung abscess	2
Pneumoconiosis	33
Pneumonitis	10
Bronchitis and emphysema	104
Pleural thickening	569*
Miscellaneous	158

* Some of these were almost certainly of tuberculous origin.

B. With Evidence of Pulmonary Tuberculosis, including Healed Lesions (1,435 Cases)

(1) Known cases	140
(Improved or no change, 130; relapsed, 10)	
(2) Newly discovered:	861 (2.5%)
(a) Requiring no further action	434 (1.3%)
(Including 537 healed primaries)	
(b) Showing significant lesions	427

C. Analysis of Significant Lesions

(a) Extent of disease:	
Unilateral	275 (63.4%)
Bilateral	159 (36.6%)
(b) Disposal:	
Observation	346 (1.0%)
10.8% of these were put on modified work	
Treatment	88 (0.3%)
(c) Presence of symptoms (Table III):	

TABLE III

Disposal	With Symptoms	Symptom-free	Total
Observation	105 (32.0%)	241 (68.0%)	346
Treatment	46 (52.3%)	42 (47.7%)	88

(d) Sputum results in the 88 treatment cases:

None	34
Negative	32
Positive	22

(e) Age groups of significant lesions found in first 20,982 examinees (Oct. 1943-June 12, 1944) (Table IV):

TABLE IV

Age:	14-24	25-34	35-44	45-54	55+	Total All Ages
M ..	14 (0.8%)	40 (1.1%)	59 (1.4%)	27 (1.7%)	8 (1.1%)	148 (1.2%)
F ..	42 (1.1%)	38 (1.4%)	20 (1.2%)	6 (0.9%)	1 (0.6%)	107 (1.2%)

Comments

If the population of Middlesex be taken as 2,000,000 it can be calculated that there are approximately 1,200,000 persons in the 14-55 age group. Allowing that the age distribution of the females in the above survey is very skew, being excessively overweighted at ages 14-24, it appears that there are probably some 3,000 undiagnosed cases of pulmonary tuberculosis in the county in need of treatment, and that half of these cases are without symptoms.

A CASE OF LEFT-SIDED APPENDICITIS

BY

J. W. L. HADDON, M.B., Ch.B.

Resident Surgical Officer, Beckett Hospital, Barnsley

Although left-sided appendix is by no means rare, the following case is interesting in that a full examination was possible later in the post-mortem room and an unusual condition found.

Case Report

A soldier aged 19, three months convalescent from a subtotal thyroidectomy for Graves's disease, was admitted to hospital on March 21, 1945. He was in a very nervous and toxic state, and gave a history of severe abdominal pain, which had started suddenly 36 hours previously and become progressively worse. The pain was continuous in character, and was at first generalized and was accompanied by nausea, but had since become localized to the hypogastrium and medial side of the right iliac fossa; he had vomited twice just before admission. There was no history of dysuria, and the bowel actions had been normal. Previous history did not give any indication of gastro-intestinal disease.

Diagram showing the abnormal position of the abdominal viscera, with the restrictive band

Abdominal examination showed slight distension, with rigidity over the whole lower half of the abdomen; and acute tenderness localized to the hypogastrium and right iliac region. Auscultation revealed a "silent abdomen." Per rectum, he was tender anteriorly, high up. His general state was poor, with dehydration and a rapid pulse which showed occasional extrasystoles. A diagnosis of early diffuse peritonitis, secondary to a perforated inflamed appendix, was made, and operation arranged accordingly.

Operation.—The abdomen was opened through a right gridiron incision as there was no clinical indication of an abnormal situation of the appendix, and purulent fluid escaped. On inspection rather the appendix nor the caecum could be seen, and their absence was confirmed by finger exploration—the right iliac fossa being apparently filled with distended coils of small gut only. The incision was closed and replaced by a right lower paramedian incision. This revealed a long gangrenous appendix lying obliquely across the left lower abdomen, from left to right, with the tip reaching the recto-vesical pouch. The caecum was occupying the left iliac fossa, together with the sigmoid colon, and it was ascertained that the liver was in its normal situation; but, apart from this, no further exploration was attempted, in view of the patient's critical state, and appendicectomy with suprapubic pelvic drainage was carried out. Intravenous infusion was started, and an attempt was made to institute continuous duodenal suction; but the man proved more intractable and refused to tolerate either form of treatment, repeatedly pulling out both Ryle's tube and intravenous cannulae.

He became progressively worse, developing paralytic ileus and dying on the fifth day. Permission for a "limited" necropsy was granted.

Post-mortem Findings.—On opening the abdomen the small bowel was found to be entirely confined to the right side, with the caecum and ascending and descending colons occupying the left. The ascending colon passed obliquely upwards and to the right to join the transverse colon at a normally situated hepatic flexure, the ascending colon being maintained in its abnormal site by a thick band, 2½ in broad, between its middle third on the left side and the transverse mesocolon. The appendix arose from the right side of the caecum, and the ileum entered it towards the right side on its postero-lateral aspect. The jejunum started at its junction with a vertically descending third part of the duodenum, on the right-hand side of the superior mesenteric artery. No other congenital abnormalities were found. (See Diagram.)

Commentary

I could not find any evidence of inflammatory adhesions, and there were no enlarged or calcified mesenteric glands, so it must be presumed that the band from the ascending colon was of congenital origin; further close inspection of the band showed fairly large vessels coursing in its substance, derived from the right colic artery and distributed to the colon, suggesting that it was a contracted right mesocolon.

A so-called "wandering caecum," due to excessive rotation of an unduly mobile caecum, was excluded by the position of the appendix and ileo-caecal valve on its right side, and further proof of the congenital origin of the condition was supplied by the abnormal site of the duodeno-jejunal flexure to the left of the superior mesenteric artery.

From these findings it is suggested that the case described is a result of rotation of the mid-gut loop, which normally takes place at the beginning of the tenth week of foetal life during the process of reduction of the "physiological umbilical hernia"; the colon and caecum, with the attached post-arterial mesentery, being allowed to enter the abdominal cavity first, instead of the normal mid-gut and pre-arterial mesentery—probably as a result of a lax umbilical ring. As a result of this mechanism, the later return of the mid-gut loop tends to displace the vitelline artery and hind-gut, with its post-arterial mesentery, to the left and dorsally, thus accounting for the left-sided position of the large bowel. Some attempt at normal fixation of the mesenteries had taken place, as is shown by the hepatic flexure occupying its normal position, in contradistinction to the more usual U-shaped transverse colon of non-rotation of the mid-gut loop, and this partial fixation probably prevented the marked tendency to volvulus around the superior mesenteric pedicle in early infancy, of which Dott describes two cases (*Brit. J. Surg.*, 1923, 11, 251).

An unusual feature of the clinical findings was the presence of signs and symptoms in the right iliac fossa, at a point remote from the actual position of the appendix; but its deep pelvic situation might have accounted for this.

I am indebted to Dr. Ponder, county medical officer for Kent, and Mr J. W. D. Buttery, medical superintendent of the Royal Victoria Hospital, Folkestone, for permission to publish this case.

A. Louis (*Thèse Paris*, 1945, No. 95), who records an illustrative case in a girl aged 19 months, came to the conclusion that the best treatment of Still's disease at the present time consists in intramuscular injection of gold salts.

Medical Memoranda

Four Cases of Hemicolectomy

Below are presented accounts of four cases of hemicolectomy performed for different and rare conditions.

CASE REPORTS

Case 1.—Man aged 56. On admission the patient gave a history of increasing constipation for the past six months, together with colicky abdominal pain about seven hours after meals, loss of weight (one stone), and recent onset of vomiting after meals. On examination a palpable mass was felt occupying the right iliac fossa and right hypochondrium, which was not tender, but which was fixed to the posterior abdomen. **Operation.**—Heavy spinal anaesthesia. A plasma drip was started and a transverse muscle-cutting incision made. On exploring the abdomen an ileo-colic intussusception was found, extending as far as the middle of the transverse colon. It was possible to reduce the intussusception only up to the hepatic flexure, so it was decided to undertake a hemicolectomy, removing the terminal ileum, caecum, ascending colon, and hepatic flexure, and performing an ileotransversostomy. The patient made an uninterrupted recovery. The cause of the intussusception was a lymphosarcoma of the terminal ileum.

Case 2.—A woman aged 70. This patient was admitted as an emergency case (? acute appendicitis). She had complained of colicky abdominal pain in the umbilical region for the past eight hours and also of pain in the right iliac fossa. A history of a similar attack two months before was given. The temperature was 99° and the pulse 74. On examination a mass about the size of a hen's egg was palpable through the abdominal wall. **Operation.**—Heavy spinal anaesthesia. A plasma drip was started and a transverse muscle-splitting incision made. On exploring the abdomen an appendix 4 in. long, thickened and hard, was found. This thickening and hardness extended to about a third of the caecum. A diagnosis of carcinoma of the appendix was made, and a hemicolectomy was performed. The terminal ileum, caecum, ascending colon, and hepatic flexure were removed and an ileotransversostomy was done. The patient made an uninterrupted recovery except for an intramural abscess which developed at the outer part of the incision. On microscopical section an adenocarcinoma involving the appendix and extending into the caecum was found.

Case 3.—This patient, a woman aged 60, was admitted as an emergency case with a two-days history of central abdominal pain, colicky in type, and vomiting which began about two hours after onset of pain. This vomiting was not marked until just before admission to hospital. The bowels had moved on the day of the onset of abdominal pain, but had only a slight motion the next day; thereafter neither faeces nor flatus was passed. On examination the lower abdomen was distended, chiefly in the right iliac fossa; there was also tenderness over the lower abdomen. On auscultation peristalsis was increased; the general condition was good. **Operation.**—Heavy spinal anaesthesia. A plasma drip started. A made, the caecum black, and friable, also involved; the caecum and ascending colon had twisted anti-clockwise on the mesentery. The volvulus was apparently caused by a very long mesentery to the right colon. As the general condition was good, it was decided to carry out a hemicolectomy; the ileum, caecum, ascending colon, and hepatic flexure were removed and an ileotransversostomy was performed. The patient made an uninterrupted recovery.

Case 4.—A man aged 62. This patient was admitted as an emergency case with a two-days history of lower abdominal pain, colicky in nature, and vomiting soon after. On the day of admission vomiting (dark brown in type) had been continuous. He had been constive since the onset of abdominal pain and had passed neither flatus nor faeces on the day of admission. On examination the lower abdomen was distended (most markedly in the right iliac area) and was tympanic on percussion; there was also lower abdominal tenderness. On auscultation peristalsis was increased. Blood pressure was 110/82. **Operation.**—Cyclopropane anaesthesia. A plasma drip was started immediately. A right paramedian incision was made; there was volvulus of the caecum and the proximal half of the ascending colon, non-viable, friable, and blue-black in colour. A hemicolectomy was performed, removing the terminal ileum, caecum, ascending colon, and hepatic flexure, and ileotransversostomy was carried out. The patient developed pneumonia and died three days after operation.

HUGH MACCARTHY, F.R.C.S.I.&Ed., M.R.C.P.I.

- Allergy to Egg-prepared Vaccines

A case is here reported of an alarming reaction to the egg allergen in typhus vaccine. One previous case has been found in the literature, and more examples of similar reactions to preparations from egg media may be expected. Oral desensitization for six months enabled this patient to take 60,000 times the dose of allergen originally causing symptoms and to eat eggs with impunity. But skin tests were unchanged, and

it would have been dangerous to attempt further inoculations. A simple precaution before giving injections of such vaccines would be to ask the question, "Do you eat eggs?"

CASE RECORD

In Nov., 1943, an airman was admitted to No. 1 N.Z. General Hospital, Middle East Forces, in a state of severe collapse, having vomited blood and become acutely breathless and then comatose. He had an urticarial eruption and his respiration was asthmatic. By next morning he had completely recovered. He had been allergic to eggs all his life—35 years—and was usually able to avoid egg foods by their taste. But if he happened to swallow the food he would vomit, or, if there was no vomiting, he would get oedema of the lips, tongue, and larynx, asthma, urticaria, and general shock. He had never before vomited blood or passed into coma, and as he was at a meal when the symptoms came on he concluded that the rissoles contained egg. Further inquiry, however, showed that he had had his first antityphus inoculation 15 minutes before this meal. It was then clear that his reaction was due to the introduction of a large amount of egg protein parenterally. An extract of egg was made, and strongly positive scratch tests were obtained both in the patient and in a subject passively sensitized by his serum.

Oral desensitization was then started, daily doses being given of a quarter of a teaspoonful of a 1:2,500 dilution of egg in water. At first this caused a mild reaction in the form of nausea and tingling of the lips, which lasted about half an hour. This reaction passed off in a few days, and the dose was increased by 50%. With a steady increase in this manner he continued the treatment until in July, 1944, he reached the dose of one raw egg daily, which has been continued since. On two occasions the sensitivity has shown signs of returning—once with a nasal cold and once when he stopped treatment for a few days.

In Sept., 1944, further scratch tests were made with egg extract and with undiluted typhus vaccine. Both gave strong reactions (3 plus), of no less intensity than before desensitization.

DISCUSSION

The preparation of vaccines from viruses and rickettsiae on egg media is a recent method of which more and more examples will be seen in the future. And since a small section of the population are highly allergic to egg protein, this will lead to some severe or even fatal reactions.

For the following list of vaccines prepared on egg media and manufactured on a commercial scale I am indebted to Major E. C. Van Rooyen, R.A.M.C.

Typhus	Prepared from yolk sac
Yellow fever	" " egg embryo
Influenza	" " "
Smallpox egg-lymph	" " allantois

An alarming reaction from the egg allergen in yellow-fever vaccine has already been reported by Swartz (1943), his patient developing asthma, gastro-intestinal allergy, and angioneurotic oedema a few minutes after the injection. My own patient gave a history of receiving yellow-fever inoculations without any ill effects, and apparently his sensitivity was to a yolk allergen not present in egg embryo.

The response to desensitization is in keeping with atopic sensitivities in general. At the outset the airman was sensitive to even the minute quantities of egg protein which could get into his circulation without being digested. Prolonged desensitization enabled him to take these minute amounts with impunity, but not the relatively large doses introduced by injection or scratch test.

I wish to thank Brig. H. S. Kenrick, C.B.E., F.D., N.Z.M.C., Director of Medical Services, N.Z.F.F., for permission to publish this report.

Swartz, H. (1943). *J. Lab. clin. Med.*, 28, 1663 (quoted in editorial, *J. Allergy* 1944, 15, 241).

The 25th report of the National Council for the Unmarried Mother and her Child (117, Piccadilly, W.1) has a foreword by the president, Lord Gorell, and is signed by the chairman, Mrs. H. A. L. Fisher, to whose devoted labours he pays tribute. The report covers a period of fifteen months and is a record of strenuous, unremitting, and valuable work. Before long the Council hopes to become incorporated and enter upon a new stage of its existence. Meanwhile it has become affiliated to the National Council of Social Service while renewing affiliation to the National Council of Women and remaining a constituent body of the National Council for Maternity and Child Welfare. The Case Committee has dealt with an unprecedented number of cases, and the Ministry of Health's scheme for the care of women discharged from the Services on account of pregnancy has involved the Council in a very great deal of work. While the Council is not itself responsible for any home, nearly all the homes and hostels of the voluntary and statutory organizations are affiliated to it.

Reviews

WAR AND SOCIAL PSYCHIATRY

The Story of Psychiatry in War. By John Rawlings Rees, M.D. (Pp. 158, 10s. 6d.) London: Chapman and Hall, 1945.

Brigadier Rees, as consulting psychiatrist to the British Army, has had a unique opportunity of investigating the psychiatry of the war, which he has summarized in these Salmon lectures given in America. While he has for the most part described the work of others, he has himself been the inspiration of that work, and as such has, with the whole body of psychiatrists, Service and lay, changed the "shape" of psychiatry. The main problem of modern psychiatry is concerned not with the psychoses but with the numerous personality problems which, in certain adverse situations of work and of social environment, lead to the psychoneuroses and behaviour disorders. Methods of analytic treatment are necessarily prolonged and can, therefore, deal with only a small proportion of those who need such treatment. An effort must therefore be made to prevent even those who are predisposed from breaking down. This is the aim of social psychiatry, and the principles and means of coping with this problem in the Army have here been described. It opens up vast possibilities for civilian life in the future.

The "priorities" in social psychiatry are: first, methods of selecting the right man for the right job; secondly, prophylaxis by better training and "man management"; thirdly, morale; and, finally, treatment. The first three are fully dealt with and their methods described.

Selection.—Some points make very interesting reading; for instance, when all candidates are examined by the psychiatrist they welcome it, whereas if some only are selected for examination this implies that they are peculiar, and they dislike it. Brigadier Rees considers that the chief credential of a good psychiatrist is the personality qualification. The importance of personality qualifications is indicated in the fact that a much shorter course is required to make a good psychiatrist provided he is of the right personality. This applies also to the selection of officers: "It was early realized that in selecting men for commissioned rank the personality factor was the major consideration, provided that the candidate had adequate intelligence" (p. 72). But is personality a "factor"? Is it not the sum total of factors, of which intelligence is one? One nevertheless has an uncomfortable feeling that in assessing personality we are assessing something the nature of which is not understood or defined. For selection, the tendency has been away from laboratory tests to tests calling forth the whole personality, such as putting the officer into a difficult test situation with a number of his fellows without any instructions.

Prophylaxis.—While the author rightly stresses that those with analytic experience are the best capable of designing methods and carrying out these procedures, it is not perhaps sufficiently stressed that only by the radical investigation and treatment of the individual can the predisposing causes be rightly assessed and the prophylaxis become really effective. Without this, social psychiatry will become a superficial study and make blunders. The medical officer, says the author, has to think in terms of groups rather than of individual patients. This is true for prophylaxis, but it is not exclusively true of treatment; and it is to be questioned why the individual casualty suffering from a war neurosis should not receive the same care, say, as an orthopaedic patient, who sometimes takes months to recover.

Morale.—To many this will be the most interesting part of the work: for instance, the observations on the danger of discipline without morale. "The three main factors which make for good morale in wartime are: adequate war aim and purpose, a sense of one's competence and value, and the feeling that one matters as an individual in a group of other similar people" (p. 84). Some of these investigations confirm earlier opinions, but others gave unexpected results, such as that women (A.T.S.) in mixed batteries complained more of fear of sterility than of sex (possibly because fear inhibits sex), and that sexual disorders arose out of loneliness rather than excess of sex feeling. A hint from child psychology was found to apply also to Army recruits (p. 79)—namely, that it is best to let a recruit use his weapon first and then learn to look after it,

otherwise he loses the enthusiasm with which he started and becomes bored. Some of us wondered at the beginning of the war whether a war could be successfully fought without hate. An interesting observation regarding morale is, therefore, that the original attempt to inculcate hate of the enemy was ineffective and led to depression; also that too much realism at first encouraged anxiety. The recruit had to be inoculated into realism. The importance of morale in war has always been recognized, but never so much as in this war. On page 95 Brigadier Rees states: "Wars are won, not by killing one's opponents, but by undermining their morale." But some of us may still believe that killing them is the most effective way of undermining their morale.

In the chapter "The Way Ahead" Brigadier Rees points out the application of the findings in war psychiatry to social psychiatry in civil life. These are but some samples of the large number of interesting subjects dealt with. Altogether it is a book that everyone interested in psychiatry, and in social and industrial medicine, should read. It gives a new orientation to the practice of psychiatry, and Brigadier Rees deserves the thanks of the profession for so lucid and interesting an introduction to the subject.

HISTORY OF ANAESTHESIA

The History of Surgical Anesthesia. By Thomas E. Keys. With an introductory essay by Chauncey D. Leake, and a concluding chapter by Noel A. Gillespie. (Pp. 191, illustrated, 8s. 6d.) New York: Schuman's.

The serious study of the origins and development of a specialty augurs well for that specialty. Sturdy and well-cared-for roots can but ensure a healthy and productive tree. So far as anaesthesia is concerned an accurate and scholarly account of its history has been long overdue. The earlier appearance of such a history might have prevented both the duplication of invention and the undeserved praise for the supposed originality of the inventors.

Major Keys has obviously put enthusiasm and energy into his task and has managed to pack a remarkable amount of information into small compass. No anaesthetist will read this book without pride, nor surgeons without wonder that so much has been accomplished in the field of anaesthesia in so short a time. The emphasis on American achievement is a little heavy, and British anaesthetists may feel that the very noteworthy contribution of this country to the development of anaesthesia in the 19th century is treated rather lightly. One of the many lessons to be learnt from reading this book is that progress in anaesthesia is not to be made by a new knob here or an altered tap there. Such stories as that of diethyl ether, told by Chauncey Leake in the introductory essay, are examples to inspire those who would make real contributions to the subject.

Major Keys has made his material not only readable but enjoyable both to the medical and to the interested lay reader. For the anaesthetist, however, the book cannot be regarded as the last word on the subject. There are only some 90 pages of text, the other half of the book consisting of a chronology, lists of references, and an index. Included, also, is a short and excellent essay by Dr. Gillespie on the future of anaesthesia. Inevitably, therefore, much has had to be omitted. Thus no reference is made to Cattlin, whose revolutionary introduction, in 1803, of a reservoir bag, now frequently misnamed a rebreathing bag, made it possible to dispense with the cumbersome gasometer. Clover, an illustrious pioneer in this country, receives but five lines in the text, in none of which are even mentioned his more important contributions, such as the, to us, familiar ether inhaler and the very ingenious and accurate apparatus for the production and administration of known percentages of chloroform. They receive a bare mention in the chronology. Some of the sources might not satisfy the academic, who would dispute the superiority of an encyclopaedia over an author's own works as to what the author did or did not say.

Most of the illustrations are portraits, and but few are instructive or help to clarify the text. They provide, however, a fine picture gallery of Americans, past and present, whose names are respected in anaesthesia. Queen Victoria finds herself in strange company. Her patronage of and submission to anaesthesia *à la reine* seem little qualification for inclusion of her portrait here.

However, these are but small blemishes in an excellent little book. One hopes that it will be widely read and become a pioneer, to be followed by more exhaustive works on this subject, which will provide not only interest for the clinician but also a detailed source of reference for the research worker in anaesthetics.

COSMETICS

Modern Cosmetology. By Ralph G. Harry, F.R.I.C. Second edition. (Pp. 432; illustrated. 35s.) London: Leonard Hill Ltd. 1944.

This book had a very good reception when first published in 1939. There are considerable alterations in the new edition. The book has grown very greatly, having expanded from fewer than 300 to over 400 pages, and is now embellished with numerous figures, including 8 coloured plates. It may be added that, whereas it was originally published in New York, it has crossed the ocean, notwithstanding the difficulties of war, and is now published in London. Although it has greatly increased in size the paper used is much thinner, and it has diminished in bulk and is very convenient to handle.

The new edition is fortified by a foreword from Dr. P. B. Mumford, who gives it his blessing. The scientific approach to the whole subject, which we noted with satisfaction in the first edition, is still well maintained—perhaps this is in large measure due to the fact that Mr. Harry is an original investigator of some experience. He himself has worked particularly on the conditions necessary for the preservation of oils. These compounds are of much importance in the manufacture of many forms of cosmetics, and they are very liable to become rancid owing to the development of a certain degree of oxidation in them, and rancidity spoils any cosmetic preparation. This tendency can be controlled to a very large extent by the help which certain anti-oxidants give to the keeping qualities of various oils. His experiments show that gum guaiacum is a very good anti-oxidant which has the advantage that, unlike several other compounds that have been used for the purpose, it appears to be quite innocuous.

This volume includes a consideration not only of creams and powders but also of the cosmetic problems presented by the hair, the teeth, the nails, and, in fact, by all the cutaneous appendages. Naturally it overlaps the domain of the skin physician, but the author is extremely careful not to trespass too far into pathology and therapeutics, and there is no doubt that the dermatologist can profit a great deal from study of this book; in fact, even more from the present edition than from the original one. On the whole the illustrations are opposite and useful, but it is doubtful whether the coloured photomicrographs of the human skin and scalp are valuable enough to justify the additional cost they must involve. They throw very little light upon the problems with which cosmeticians are concerned. This, however, is a very minor blemish, if indeed a blemish at all, and we have no hesitation in recommending *Modern Cosmetology* to all concerned with the enhancement of human beauty.

Notes on Books

Dr. ARLETTE BARBEQUOT-BUTAVAND has produced a book—*Cahiers de Dessins d'Anatomie*—for the use of the hospital attendants and nursing staff of the Medical School at Lyons. It is issued by J. B. Baillière et Fils, of Paris, in two parts, each containing 57 plates and comprising 203 separate figures. These consist of a series of anatomical drawings in simple outline, with brief legends and names of the principal parts, supplemented by occasional comments. The drawings are arranged in copybook form, the plates being on one side of the opened book—the left—whereas the opposite page on the right is left blank, to be filled in by the pupil with notes or copies of the printed drawings, which it is suggested may be coloured so as to distinguish bones, arteries, veins, nerves, and muscles from one another. The principal object which the author has had in mind is, he states, twofold: since anatomy is easily understood and impressed on the memory by drawings, to provide something concrete, which will enable each pupil to develop his own powers of observation and dexterity in drawing; and at the same time to cultivate his visual memory. He also recommends that pupils should, when possible, supplement the drawings on the printed page by original drawings from Nature, and thus increase the value of their course of study and of the books they read and benefit them in the exercise of their profession. In these days, when hospital attendants, nurses, and doctors of different nationalities frequently

become associated in their work, the publication of these two "Cahiers" should be no bar to their use by English-speaking readers, but, on the contrary, a distinct advantage, since it would tend to familiarize them with the names of the various parts and organs of the body in the French language.

The importance of the care and housing of the aged is being increasingly realized. A pamphlet entitled *Bucks Old People's Welfare* tells the story of the formation of a county committee for that purpose at Aylesbury on Feb. 3, 1945. Sir Leonard West, chairman of the Buckinghamshire County Council, presided, and every branch of social endeavour was represented. It was pointed out by Mrs. Keeling that it was the transfer of responsibility for supplementary pensions in December, 1940, to the Assistance Board that had brought to light the fact that many old people were living alone under the most unfavourable conditions. The aim of this committee was to see that such were not only fed, clothed, and sheltered "in a negative kind of peace" but enabled to spend what was left of their lives in "positive happiness." In pursuit of this laudable, if difficult, objective, representatives were appointed to look into the situation and to report later with suggestions to an adjourned conference. The body of this booklet discusses, in an interesting way, both short-term and long-term policy for remedying a gap in our social services still inadequately filled, though some real success has been achieved already. It is evidently written by an enthusiast for the subject, with definite and clear-cut ideas. Copies may be had from the printers, Hunt, Barnard and Co., Aylesbury, price 1s. 2d. post free.

The welcome we gave to the first edition of Dr. JULIUS BAUER's *Constitution and Disease* can be given with equal cordiality to the second (William Heinemann; 21s.). That this has been called for within eighteen months of the publication of the original edition proves its usefulness. For too long the genetic factor in disease received scanty and intermittent attention, and although this is being corrected it has not been easy to obtain the evidence in a compact form such as is now possible from these pages. In this new edition the text has been amplified, the bibliography has been added to considerably, and it is now, as it should be, provided with an adequate index.

We have noticed in these columns several books on the population problem. Mr. MARK ABRAMS's little book, *The Population of Great Britain: Current Trends and Future Problems* (George Allen and Unwin; 3s. 6d.) is among the best; it is very clearly written and objective. It can be read through in an hour and provides any intelligent person with an adequate basis of knowledge. We may add that, unlike so many wartime books, it is pleasant to look at and read.

Preparations and Appliances

VALVE DISK FOR CIRCLE ABSORBERS

Dr. J. CLUTTON-BROCK (Lincoln) sends the following description of a new valve disk for circle absorbers:

This device consists of a disk of thin flexible portex joined concentrically to a thin perforated disk of metal.

I have found these disks very satisfactory in my absorber as they only weigh 13 gr. as opposed to 34 gr. for a standard metal disk of the same size. There is no tendency to blow back at a pressure of 200 mm. Hg. Although they are, perhaps, a little heavier than a similar bakelite disk, there is no question of warping, and I have found most bakelite disks definitely not very flat. The two disks are joined together at the point A by a small aluminium rivet. The thickness of the metal disk is 0.005 in., and the portex 0.007 in. The thin portex disk lies on the knife edges and makes a perfect airtight seal.

SULPHATHIAZOLE SUSPENSION

Messrs. Menley and James, Ltd., now offer for sale "mickraform" sulphathiazole suspension. It is a sterile suspension containing 20% sulphathiazole in very fine crystalline form, far finer than ordinary crystals. Since sulphathiazole has a low solubility, these smaller crystals give a much better chance of the sulphathiazole getting into solution. The suspension can be applied much more effectively than powder to deep wounds. It has a pH between 5.5 and 6.5, and is said to be stable.

Supplies again available

After a considerable lapse of time the water-soluble 'Roche' vitamin K analogue is again available in ampoule form. 'Synkavit' ampoules contain the water-soluble tetrasodium salt of 2-methyl-4-naphtho-hydroquinone diphosphoric acid and are suitable for intramuscular or intravenous injection.

'SYNKAVIT' VITAMIN K ANALOGUE

'Synkavit' oral tablets, each containing 10 mg., are issued in packings of 20, 100 and 500. Bile salts need not be administered with 'Synkavit'.

'Synkavit' ampoules of 1 c.c., each containing 10 mg of the active substance, are issued in boxes of 6 and 50.

An Effective Analgesic

WHILE modern chemical research has evolved many and diverse analgesics the popularity of acetylsalicylic acid and its reputation for effectiveness remain. Nevertheless, some physicians have hesitated to employ it owing to its tendency, in certain conditions, to irritate the stomach.

In "Alasil," however, the desirable therapeutic effects of acetylsalicylic acid are maintained by combining the acid with Dibasic Calcium Phosphate and "Alocol" (Colloidal Hydroxide of Aluminium), a powerful gastric sedative and antacid. Thus "Alasil" helps to solve the problem of administering acetylsalicylic acid in an effective form, even to patients with sensitive stomachs.

The advantages of "Alasil" have been well proved in practice. Experience shows that it can be prescribed with safety to patients of all ages.

Each tablet contains 5 grs. Acetylsalicylic Acid, 6 grs. "Alocol" (Colloidal Hydroxide of Aluminium) and 1½ grs. Dibasic Calcium Phosphate.

Alasil

M322

MORYL

TRADE MARK BRAND

CARBACHOL

Parasympathetic Stimulant

A powerful stimulant of the parasympathetic nervous system, chemically related to acetylcholine but more active and more stable.

Indicated more especially in post-operative intestinal stasis and urinary retention. 'Moryl' is also useful in eclampsia and pre-eclamptic conditions, hypertension, paroxysmal tachycardia, anxiety neurosis, cœdema, and glaucoma.

In ampoules, oral tablets and special solutions for glaucoma and cœdema.

TETRONOX

TRADE MARK TABLETS BRAND

Hypnotic—Sedative

barbitone with phenacetin, pherazone, hexamine and magnesium peroxide.

Enhanced power of barbitone through careful combination with other drugs—reduced toxicity, no cumulative action or injurious effects on circulation, respiration, or gastro-intestinal tract.

KEPLER[®] BRAND

COD LIVER OIL

with MALT EXTRACT

A valuable supplementary source of Vitamins A and D, with readily assimilable fat and carbohydrate.

'Kepler' Cod Liver Oil with Malt Extract contains Cod Liver Oil 23% v/v with Malt Extract; each tablespoonful provides not less than 3500 International Units of Vitamin A and 500 International Units of Vitamin D.

BURROUGHS WELLCOME & CO.

(The Wellcome Foundation Ltd.)

LONDON

THE SAFE LAXATIVE

Constipation is probably the most frequent cause of ill-health, and it is the concern of those who tend the sick to relieve their patients from this disorder.

In this connection 'California Syrup of Figs' perfectly meets the need for a safe yet efficacious agent. Completely void of mineral or synthetic cathartics, it is corrective not purgative, and re-educates the bowel to normal function.

Its pleasant taste and simplicity of dosage makes 'California Syrup of Figs' the laxative of choice for young and old alike. It may safely be employed either in occasional constipation or for routine use in everyday family life.

'CALIFORNIA SYRUP OF FIGS'

Contains approximately 27.8% Ext. Senn. Fol and 27.0% Syrup Ficorum (1 in 10) with carminative, sweetening, and flavouring agents.

179, ACTON VALE, LONDON, W.3.

3 water-soluble vitamins in ONE tablet

Stomatitis, anorexia, gastro-intestinal disturbances, states of debility, fatigue, and certain skin disorders are often associated with a lack of the water-soluble vitamins, nicotinic acid, B₁, and C. When these vitamins are supplied as an adjunct to treatment an improvement is usually noted. 'Nicorbin' tablets containing these nutrients, given thrice daily, supply the average adult requirement.

During pregnancy and lactation, and during the process of wound healing the increased demands for these vitamins are met by supplying 'Nicorbin'. Whenever, from deficient intake or excessive physiological need, these water-soluble vitamins are required, 'Nicorbin' will prove valuable.

NICORBIN

COMPOSITION Each 'Nicorbin' Tablet contains:—Aneurine Hydrochloride (vitamin B₁) 1 mg. Ascorbic Acid (vitamin C) 25 mg Nicotinic Acid (P.P. factor) 10 mg.

GLAXO LABORATORIES LTD., GREENFORD, MIDDLESEX. BYRON 3434

CHLOROFORM

OUR association with the manufacture of Chloroform dates back to 1847, when Sir James Young Simpson demonstrated its anaesthetic properties and approached Dr. Thomas Smith (Founder of our Firm) with a view to obtaining sufficient quantities to carry out his pioneer work.

Our long experience enables us to produce an anaesthetic chloroform of standard composition, UNSURPASSED FOR RELIABILITY, and answering the tests of all pharmacopoeias.

DOSAGE AND EFFECTS OF CHOLINE CHLORIDE

In a recent letter to this *Journal* J. A. Barclay and co-workers¹ have suggested that the dosage of methionine and choline should be much higher than the amounts used in the therapeutic trials which have been reported in the *Journal*² and elsewhere. They calculate that the curative dose in man would be 20 grammes of choline a day for two or three weeks, or 20 to 60 grammes of methionine a day for a period as yet undetermined. For the moment such quantities of methionine can be dismissed as unobtainable for general therapeutic use. Choline is a simpler and cheaper compound, and as it is likely to be the subject of further therapeutic trials in diseases of the liver and kidneys and in protein malnutrition, the following observations on dosage and toxic effects may be of value to intending prescribers.

Twenty years ago physiologists and physicians were interested in choline chiefly because it was the parent substance of acetyl choline. It has, in fact, much the same action on the autonomic nervous system as acetyl choline, acetyl- β -methyl choline, and carbamyl choline, though it is far less potent. Sollman³ states that cats show no ill effect after the slow intravenous injection of 15 mg. per kilogramme of body weight, 35 mg. per kg. are fatal. As the choline is rapidly destroyed, 0.8 to 0.9 mg. per kg. a minute may be injected "practically indefinitely." This corresponds to a dosage of approximately 3 grammes an hour in man. Slow intravenous injections have been recommended for the treatment of paralytic ileus, and this probably represented the only therapeutic indication for choline until the last two or three years. Both the *British Pharmaceutical Codex* (1934) and the *Extra Pharmacopoeia* (Martindale, 1941) give the dose for this purpose as 10 grains (0.6 g.) intravenously, though the latter subsequently recommends "10 g. in 180 ml. of normal saline," which is presumably a misprint.

During the past decade a considerable literature has accumulated on the nutritional significance of choline. It is now regarded as an important constituent of the vitamin B complex which is concerned in the transport of fat in the body and is essential for the health of the liver and the kidneys. As a consequence choline chloride has been used in the treatment of acute and chronic disease of the liver in man. On theoretical grounds more might be expected of choline in chronic enlargement of the liver and the fatty type of cirrhosis than in acute hepatitis or in the shrunken liver of atrophic cirrhosis. Therapeutic trials of choline in cirrhosis so far reported have been

carried out without controls, and a decisive answer will not be obtained until a large number of cases is collected and alternate patients are treated with and without the drug. Reports on the treatment of isolated cases of acute hepatitis or acute necrosis are likewise suspect. It is difficult to follow Barclay's argument that results become more convincing when they are buttressed by metabolic data; changes in metabolism are just as much subject to the statistical law of variation, and demand just as careful controls, as clinical improvement or deterioration. Our purpose, however, is not to assess the clinical value of choline but to discuss the dosage by mouth and the possibility of toxic effects from long-continued administration.

The daily requirement of choline chloride has been estimated approximately in the growing rat. Griffith⁴ puts it at 4 to 6 mg., and Engel⁵ at 10 mg. for a 40-gramme rat. This works out at 250 mg. per kilogramme of body weight. This figure probably represents the order of dosage required in man, for, although the growing rat has a high rate of metabolism and therefore uses a lot of choline compared with an adult man, this is balanced by the fact that the dosage of vitamins in disease has to be much higher than the maintenance dose. In the dog, Fouts⁶ has used 100 mg. per kg. of body weight to counteract the effects of a low protein diet, but Kaplan and Chaikoff⁷ found a higher dose necessary to exert a curative action on the fatty liver of experimental animals. They had to give 400 mg. of choline chloride per kg. for more than three weeks to reduce the fat content of the liver of the depancreatized dog to normal levels. Dosage in man has hitherto been a good deal lower. Broun and Muether⁸ treated four patients with cirrhosis with choline chloride in a dosage of 1 g. daily for periods up to two years. Russakoff and Blumberg⁹ in ten cases of cirrhosis gave up to 6 g. of choline chloride a day in divided dosage. One of their patients, who was given 0.5 g. of choline chloride on an empty stomach, complained of nausea, which was associated with a slight drop of blood pressure and slowing of the heart; otherwise there were no ill effects. Their highest single dose appears to have been 15 g. Richardson¹⁰ gave 15 g. of choline chloride a day for eight days to sixteen patients with infective hepatitis without appreciable effect.

Only one author has described ill effects from continued administration of choline chloride, and his observations have not been confirmed in man. Davis¹¹ has reported that the red cell count in dogs falls when they are given choline chloride by mouth for fifteen days or longer. He observed a fall when the choline was given in a single dose of 8 mg. per kg. a day, but the effect was greater when 10 mg. per kg. of choline chloride was given thrice daily.¹² The anaemia was attributed to dilatation of the blood vessels by the choline and increased supply of oxygen to the bone-marrow. Davis suggested the possibility that dogs prepared in this way might be used for the biological assay of liver extracts for the treatment of pernicious anaemia.

¹ *J. Nutr.*, 1945, 22, 239.² *Ibid.*, 1942, 24, 174.³ *Ibid.*, 1943, 25, 217.⁴ *J. Biol. Chem.*, 1937, 120, 647.⁵ *J. Amer. med. Ass.*, 1942, 118, 1403.⁶ *Ann. intern. Med.*, 1944, 21, 848.⁷ *British Med. J.*, 1945, 2, 156.⁸ *Amer. J. Physiol.*, 1944, 142, 65.⁹ *Ibid.*, 1944, 142, 402.¹⁰ *British Medical Journal*, 1945, 2, 298.¹¹ *Ibid.*, 1945, 1, 415.¹² *Manual of Pharmacology*, 6th ed., Philadelphia, 1942.

Davis¹³ has also reported that choline chloride in a daily dose of 100 mg. by stomach tube is effective in partially reducing cobalt polycythaemia in rabbits. These experiments have not been supported by observations on man. Cartwright and Wintrobe¹⁴ found that choline chloride had no effect on the blood count in man when given in doses of 10 mg. per kg. of body weight orally three times daily, and choline chloride has been tried without success in a smaller dosage in polycythaemia in man.^{15 16} Finally, there is the paradox that Moosnick, Schleicher, and Peterson¹⁷ report the cure of a refractory case of pernicious anaemia by means of intravenous injections of choline chloride, 1 g. daily. They suggest that fatty infiltration of the liver prevented successful elaboration of the liver extract and that the infiltration was removed by the choline.

The conclusion from the literature is that the effective dose of choline chloride for the treatment of disease of the liver or kidneys, and for disturbances of nutrition or metabolism, is likely to be at least 100 mg. per kg. of body weight, or 6 g. a day in an adult man, and it might be three or four times as high. In other words, the curative dose of choline chloride must approach close to the toxic dose. The danger is a sudden flooding of the circulation with choline and consequent depression of the heart and blood pressure. This has happened with as little as 0.5 g. taken on the fasting stomach in man. This danger and other disadvantages may be circumvented by intravenous drip therapy, as Barclay suggests, but whatever expedient is used treatment with choline will need careful supervision if it is to be both effective and safe. The risk of depression of the bone-marrow can probably be discounted, but it would be well to keep a watchful eye on the blood count until more is known about the reaction of the human marrow to high dosage. Furthermore, we cannot regard the therapeutic failure of choline in human polycythaemia as completely demonstrated until maximum tolerated doses have been tried.

LUNG DISEASE IN COAL-MINERS

do justice to the fascinating material in the third report recently issued by the Medical Research Council's Committee on Industrial Pulmonary Disease¹⁸ would tax the ingenuity of the most experienced abstracter. In a small volume of 94 pages is accumulated what must surely be a unique series of experimental attacks on the fundamental problems of coal-miner's disease, carried out quietly and with restraint at a period when the world's greatest war was being waged. It will be recalled that the committee's scheme of inquiry included a medical survey and related pathological studies of chronic pulmonary disease in South Wales in terms of the environmental background. Previous reports have dealt with these facets, ranging over physical, chemical, and petrological no less than medical peculiarities. The third report is a complementary one, and describes the experimental problems which have been

encountered. It must be a source of satisfaction to the committee that a convincing answer to many queries has been given by their colleagues in the laboratory.

Before attempting to give some idea of what awaits the reader it will be useful to remind him of the trend of previous investigations sponsored by the committee. A careful survey established beyond doubt the responsibility of air-borne dust as a factor of first importance in the production of coal-miner's disease. Chemical and petrological investigations of the nature of such dust, and of the coal seams and adjacent rock strata from which the dust is derived, brought out the complexities of the disease-producing agent, and suggested that variations in the incidence of pneumoconiosis might depend on differences in the dusts. It can now be stated that the composition of mineral residue obtained from the lungs varies with the occupation of the miners, according to differences in the dust-producing strata in which the men work. Although anthracite colliers show no significant increase in dust or total silica or quartz with increasing degrees of fibrosis of their lungs, the group as a whole has an increased quartz residue when the picture of silicotic nodulation is impressed on the pulmonary tissue. Prof. E. J. King and his co-workers consider that quartz, rather than mica or kaolin, constitutes the chief hazard, though its activity may be modified by the other dust components. Some idea of the relative importance of the various dusts as agents of disease may be obtained by introducing them into the lungs of experimental animals—a method developed by the late Prof. E. H. Kettle. Belt and King find that the purest coal dust, whether anthracite or steam coal or bituminous, has a low pathogenicity. Animals so treated show little fibrosis in their lungs even after the lapse of long periods of time. As the content of siliceous material in the coal dust increases so do its pathogenic properties. Mixing quartz dust with shale dust, which is lowly pathogenic, substantially reduces the harmful nature of the quartz. Mixtures of quartz dust and coal give a confluent fibrosis more closely allied to that seen in coal-workers than the lesion resulting from pure quartz dust. It is apparent that many factors are concerned in the production of the South Wales pulmonary disease; among them are the quantity of siliceous matter in the inhaled dust and the presence of mineral matter which modifies the deleterious action of silica. The problem is complicated by the observation that some siliceous dusts are harmful and others relatively harmless; so far there is no clear explanation for these differences. In accounting for the injurious effect of silica the possibility of a toxic action on tissue cells when it is in solution has to be considered. The difficulties encountered in establishing this hypothesis are set out in the admirable report of Prof. King, who has earned the gratitude of at least one reader for the lucidity he has brought to a forbidding chemical labyrinth. In general it seems to be true that the more soluble a siliceous dust the greater its toxicity; but there are many exceptions to this generalization, and further investigation is required for a satisfactory answer.

What, then, is the present position of the coal-miner's problem? The third report of the Medical Research Council's committee suggests that quartz is probably the

most noxious factor, but that its action is modified by admixture with other substances. The South Wales dust is composed of small amounts of quartz mixed with large amounts of coal and other minerals, either of which may contribute its part or even exert an antidotal effect on the action of the quartz. This sort of explanation might account for the decrease in incidence of pneumoconiosis among colliers in South Wales with the rank of the coal mined, from high in anthracite to low in bituminous coal. In other words, there must be considered a number of possibilities, such as a generally higher dust concentration in anthracite mines, differences of interaction of quartz with different types of coal, or differences of modification of quartz effect because of varying mineral composition of the shales and other strata associated with the coal. It seems likely at the moment that all these factors are involved in causing the differences in the incidence of pneumoconiosis—a truly formidable prospect for the investigator. If the M.R.C. reports are an indication of the energy and inspiration which will be directed in the future towards a most difficult problem, there need be no room for pessimism over its solution.

THE EFFECTS OF LIGHTNING

Since Seneca, doctors and philosophers have for centuries been interested in the diverse and often bizarre sequelae of lightning-stroke, and the manner of death. Pliny's opinion that a person who has heard the clap of thunder and seen the lightning flash can consider himself safe from that particular hazard has a curious topical ring in view of the beliefs as to survival during aerial bombing and falling V1 and V2 projectiles. Among the seventeenth- and eighteenth-century writers on fulguration we can with benefit re-read J. A. Dietericus,¹ J. A. Munnich,² F. J. Baier,³ C. F. Hoffmann,⁴ and J. G. Biedermann.⁵ In the nineteenth century more serious attempts were made to study the physiology and pathology of lightning-stroke, and the monographs by Bonnet⁶ and by F. Sestier⁷ are classics. L. Weber's report on the Schleswig-Holstein disaster of 1878, in which 92 people were struck and 10 killed, may be taken in conjunction with F. Panse's account⁸ of the Königstein incident, where, out of a party of 29, 3 were killed and 26 temporarily paralysed. Charcot was particularly interested in the neurological effects of lightning—a phenomenon which he termed "keraunoparalysis". In more recent years the subject has been written up by H. A. Spencer⁹ and by M. Critchley.^{10 11}

The Goulstonian Lectures of Dr. A. J. Jex-Blake on "Death from Electric Currents and by Lightning"¹² are well remembered. This same author has lately contributed a paper to the *East African Medical Journal*¹³ dealing with modern ideas on the physics of lightning. We learn that the electrical potential between the two ends of a flash is around a thousand million volts. The current is direct, amounting to 20,000 amperes at least, and the quantity of electricity conveyed averages 20 coulombs. Most of the energy is converted into heat, but there also appear

Herzian waves (or "atmospherics") with a frequency of 20,000 or so. According to Simpson's "breaking-drop" theory¹⁴ it is considered that electricity separates whenever a raindrop breaks up into a number of smaller particles. The water becomes positively charged, the air negatively. The upward movement of warmed air brings about an electrical separation. A single flash occupies a thousandth of a second, and photographs demonstrate that it follows a meandering course with lateral branches, and has not the conventional zigzag shape depicted by artists. When lightning strikes sandy soil it may produce by fusion an irregular fulgurite or lightning-stone, reminiscent of the vitreous changes brought about in Hiroshima by the detonation of the atomic bomb.

The same issue of the *East African Medical Journal*¹⁵ contains an editorial on "What to do in a Thunderstorm." One should remain indoors, with doors and windows shut, and away from the fireplace. Telephones may be used with impunity, but the neighbourhood of the main electrical switch and meter should be avoided. The lead-in wire from the aerial to the wireless set should be fitted with a switch to permit earthing. Out of doors one should shun crowds, flocks of cattle, isolated trees, hedges, walls, and river banks. It is better for one's clothes to be soaking wet than dry. To hold up an open umbrella is unwise. The treatment for apparent death after lightning-stroke is prompt artificial respiration, continued if necessary for hours or until the body cools or rigor mortis ensues.

It is common knowledge that Great Britain is relatively immune from severe thunderstorms as compared with Kenya and South Africa. Nevertheless during the 29 years 1852-80 there were 546 fatal cases of lightning-stroke in England and Wales, and in the decade 1901-10 there were 124 deaths. A. G. S. Mahomed¹⁶ considered from an analysis of 237 fatalities that lightning storms in England and Wales are commonest on the plains and oolitic uplands, but the usual belief that lightning is more frequent along the course of rivers was not supported.

NUTRITIONAL SURVEYS IN ITALY

The I.N.R.R.A. medical programme in Italy was described at a recent Press conference in London by Dr. J. Metcalf, one of two young Harvard doctors, the other being Dr. A. Queeney, who have been carrying out nutritional surveys in that country. Dr. Metcalf explained that the I.N.R.R.A. programme had three main objectives: (1) to determine the degree of malnutrition in Italy as evidenced by clinical examination; (2) to use the results for the purpose of providing foodstuffs to meet specific needs, and (3) to bring Italian organization to a stage at which it would be able to assume responsibility. During a period of six or seven months, beginning in January last, some 34 surveys had been carried out in areas of Rome and Milan, also south of Rome, and to the north from Pisa to Ravenna. Data were obtained on the heights and weights of selected poorer children who were likely to be undernourished. The statistics were thus heavily weighted in favour of reflecting the lower levels of malnutrition in Italy, not the average nutrition. The object was to gain information rapidly, and to utilize it rather than to obtain the exact statistics desirable in an ordinary research project.

Out of some 2,500 children, about 31% showed some form of classical nutritional deficiency, and of that deficient class roughly 90% had rickets. Only 17 cases of gross inanition or profound malnutrition of the starvation type were discovered, and these were all in infants in insti-

tutions. Of the mothers examined 3.5% had classical nutritional deficiencies. Attention had been mainly directed to expectant and nursing mothers, the groups most likely to show the first evidences of malnutrition. A number of the persons examined were in refugee camps. The deficiencies most frequently suggested were in riboflavin and vitamin A.

A technical committee on nutrition had been set up by the Italian Government. Its members included eminent medical specialists, and it had issued a pamphlet as a basis for examination of the population generally, but more specifically of mothers and children. This pamphlet had been sent to about 20,000 doctors in Italy, accompanied by a record card for setting out the findings of their own examinations. The information thus gathered from the whole country was sent to the central committee, and in essence it provided a system, which was still in its early stages, for the notification of malnutrition. Dr. Metcalf believed that Italy was one of the few countries, if not the only country, which had made malnutrition a notifiable disease. The pamphlet also gave a basic food schedule for infants—a standard method which went as far as it was possible at the moment to go in this direction. Mothers and children in need would thus be enabled to obtain supplementary foodstuffs from U.N.R.R.A.; the amount and kind being determined on an economic and medical basis. The economic need must be considered independently of the medical need, because it was conceivable in such a country that a person might exhibit no signs of gross malnutrition and yet be in great need of food.

The Nutrition Committee of the Italian Government, said Dr. Metcalf, had also started a series of training courses for Italian doctors. The courses were to be carried out at five universities, and the programme in the University of Rome had already begun. Each course lasted for about two weeks and consisted of some 38 hours of didactic lectures and a similar amount of time in practical demonstrations. Doctors who had been out of contact with recent developments, especially on the nutritional side and in paediatrics and maternal welfare, would thus have an opportunity of being refreshed. Infant mortality in Italy had always been high. It was difficult to determine the actual mortality at the moment, but the general feeling was that it had not been greatly aggravated. Rickets had undergone a sudden increase during the war, but no exact comparison with pre-war figures was available. There was also an increase in tuberculosis. In view of the many other causes

acting in wartime favouring tuberculosis, such as over-crowding and the distribution of infected people among the population, this must not be regarded as attributable to malnutrition. Children's clinics in Italy, while architecturally satisfactory, appeared to be under-used. Some of the larger clinics were found to be caring only perhaps for two dozen children, whereas similar clinics in other countries would be serving in the course of the year a couple of thousand. Steps were now being taken for the clinics to be more adequately used.

RELAXIN

In 1854 Duncan¹ published his observations on "The Behaviour of the Pelvic Articulations in the Mechanism of Parturition." Ever since it has been recognized that a relaxation of the pelvic ligaments occurs during pregnancy, but only in the last two decades has the mystery of this mechanism begun to clear. In the 'twenties Hisaw and his colleagues²⁻⁵ demonstrated the nature of the relaxation

as it occurs in guinea-pigs, and found in the serum of pregnant animals of many kinds a substance which they called "relaxin." They prepared a powerful extract of the hormone from the corpora lutea of sows,⁶ and claimed that it was distinct from both oestrone and progesterone. Confirmatory evidence was published by Brouha,^{7,8} Pommerenke,¹⁰ and Abramson *et al.*,¹¹ but the discovery by de Fremery *et al.*,¹² Courrier,¹³ Tapfer and Taslhofer,¹⁴ and Haterius and Fugo¹⁵ that relaxation can be brought about by oestrogens and progesterone naturally cast doubts upon the existence of relaxin as a separate hormone. That oestrogens are capable of producing relaxation is, indeed, a fact of veterinary importance, for the consequent alteration in the morphology of the hind-quarters of cows is a cause of the fractures which occur when stilboestrol is used with a view to increasing the production of milk.¹⁶

These doubts have stimulated Hisaw and his colleagues to further research. They have now shown¹⁷ that a preparation of relaxin can be made which has no oestrogenic effect in a dose 120 times and no progestational effect in a dose 500 times that required to relax the pelvic ligaments of guinea-pigs. They showed also that relaxin not only fails to bring on the physiological effects of oestradiol and progesterone but differs from them chemically in being insoluble in fat solvents. The relaxing effect of relaxin is maximal 6 hours after injection, that of progesterone 72 to 96 hours later. The injection of progesterone into intact animals (but not into those which have been castrated and hysterectomized) is followed after the same interval by the appearance of relaxin in the blood. Progesterone, moreover, cannot bring about relaxation in castrated and hysterectomized animals. It seems probable, therefore, that the relaxation it causes in intact animals is due to the fact that it stimulates the formation of relaxin in the genital tract. Oestradiol is likewise capable of doing this in intact animals, and in castrates, but not in castrated hysterectomized females. In them, however, it potentiates the action of injected relaxin, and it has in all probability some independent relaxing activity. It is noteworthy that so far relaxin has been found only in conditions in which progesterone is normally present. One of the functions of progesterone may well be the formation of relaxin in the uterus. In unpregnant females only the concentration found in pseudo-pregnant animals can be experimentally achieved. This is one-fiftieth the concentration found in normal pregnancy, and it therefore seems likely that the placenta is the main site of formation of relaxin.

Although the changes induced by relaxin in animals are not identical with those found in women, they are similar enough to suggest that a parallel mechanism is at work. Moreover, relaxin has been found in the serum of pregnant women by Abramson and his colleagues.¹¹ The possible clinical significance of these findings is obvious, and further work on the human subject will be eagerly awaited.

The Minister of Health (Mr. Aneurin Bevan) is reported to have stated at a meeting of the Society of Physiotherapists on Oct. 20 that by the early months of 1946 he would be presenting a Bill in the House of Commons for a comprehensive health service.

ANNUAL HARVEIAN COMMEMORATION

THE PRIME MINISTER WITH THE ROYAL
COLLEGE OF PHYSICIANS

The Harveian Dinner of the Royal College of Physicians was held at the Dorchester Hotel on St. Luke's Day, when Lord Moran presided over a company numbering about two hundred. The principal guests were the Archbishop of Canterbury, the Lord Chancellor, the Prime Minister and several members of his Cabinet, the Prime Minister of Canada, Mr. Anthony Eden and other members of the late Government, the French, Soviet and Chinese Ambassadors, the Lord Mayor of London, the President of the Royal College of Surgeons, and representatives of other medical bodies, including the President and the Chairman of Council of the British Medical Association. It was a notable occasion and not least because of the blend of seriousness, wit, and brilliance as represented in the speeches of the Prime Minister, the Archbishop of Canterbury, and the President of the College.

The PRIME MINISTER who said that though he spoke as a layman he could claim many doctors in his family tree, both as ancestors and as collateral, proposed the health of the Royal College. Since the foundation of the College, over four hundred years ago, it had played a noteworthy part in contributing to the health and happiness of mankind, and it was well in these days of change when so many monuments of the past were being swept away to consider the continuity of effort directed to a single aim which the College represented.

Mr. Attlee went on to speak of two outstanding advances in medicine during the war, one of them, which would have been of special interest to Harvey himself, the development of the blood transfusion service, and the other the discovery of penicillin. But in mentioning these advances on the research side he wished also to pay tribute to the personnel of the medical profession both in the fighting Forces and in civil practice. Here he digressed to speak of the services rendered by the President to the late Prime Minister.

"We in the War Cabinet often had great anxiety owing to the voracious travelling habits of our wartime Prime Minister, and it was always a comfort to know that on these expeditions he was under the care of Lord Moran."

After saying that he could give no details of the Government's proposals for a National Health Service, Mr. Attlee proceeded:

"We seek a service which will be comprehensive in the double sense of being available to every member of the population and of covering every form of medical and allied activity. We intend to have a service in which no patient shall be without the treatment he needs through lack of money or through deficiency in or lack of organization of the necessary facilities. We need, too, a service in which professional men and women will be able to devote themselves to their great calling without financial anxiety and without in any way feeling cramped and over-controlled by regulations."

He spoke of the need for a great improvement in the hospital service in the facilities for diagnosis and treatment outside hospitals, in the number and distribution of medical men, both consultants and general practitioners, and perhaps above all in the planning and organization of all the different branches into a single integrated service. "The task is not easy, but we are going to do it. Above all we realize—no one more keenly than my friend the Minister of Health who is here this evening—that for this to be successful we must have the help and co-operation of the profession itself."

Doctors and Politicians

LORD MORAN began by giving a little ancient College history. In 1637, when the College prepared for the Government a report on the health of the people—a report which would do credit to any modern medical officer of health—it ended by proposing a Ministry of Health. The actual words were: "They suggest the provision of a commission or office of health, which has been found useful in Spain, Italy, and elsewhere." The Ministry was established nearly 300 years later. The College still made suggestions, and on the whole he thought the tempo had quickened a little! Truth compelled him to say that not all the College pronouncements were so prescient. In 1648 it

pronounced public baths hurtful to the commonwealth and cited the experience of Athens and Rome to show that they caused physical effeminacy and debauchery of manners.

Politics and medicine, Lord Moran went on, had certain things in common. The Prime Minister of one of the Dominions once said to him that the great thing in politics was to avoid mistakes, and certainly in the practice of medicine the best physician was the one who committed the fewest errors in diagnosis. How was this done? The physician who never for a moment forgot the distinction between what he knew and what he only thought he knew would not go far wrong. But if as he grew older and vainer he refused to admit that he was fallible, his mistakes would multiply. A physician who in the hubbub of success had lost his humility was not a safe guide.

A kind of success could be won in both professions by the gift of the gab. He supposed that the greatest danger to the doctor's integrity of mind was the credulity of his patients. A friend of his, one of the ablest Ministers in the last Cabinet once confided to him that at all times and in every ill he had found salvation in the manipulations of a certain gentleman.

I forget now whether he twisted his neck or merely pulled his leg. Was the quality of credulity entirely lacking from the audiences which hung on the words of politicians in Parliament and in the country? Was it not true that in a democracy the gift of public speech had an undue advantage over other qualities? And if the credulity of the public was a snare to both professions, what was the remedy? It could only be the education of public opinion.

"Will medicine and politics go forward into the future in step? I wonder. Medicine is becoming more scientific. The glittering victories she has won in the field of bacterial disease by the discovery of penicillin and by the use of sulphonamides have enriched our resources. The physician of to-day is twice as well equipped in the war against disease as he was when I was a student. The physician who knows what is wrong with a patient and has an effective remedy in his hands can cut the cable. He has no need of it. The doctor's patter has been the subject of ridicule from Moliere to Bernard Shaw, but the profession has been weaned from this patter because it has been armed. The task of the politician is less simple. Even more than the doctor he has to deal with the vapours in man's mind. But let me end my comparison of politics and medicine with this admission: that while medicine has riveted the attention and absorbed the energies of some of the ablest of our race, the government of man, which is the business of politics, is the creation of all human studies."

Responding to the toast of the guests proposed in a speech of commendable brevity by Dr. John Parkinson, Harveian Orator, the ARCHBISHOP OF CANTERBURY who enlightened the occasion with a wit that delighted everyone referred to his connection with the King's School at Canterbury, mentioning that he had only discovered that afternoon that two old boys of that school bore honoured names in the early history of the College. One was Thomas Linacre, founder and first President, and the other was William Harvey himself. Both of them were also Oxford men—one a Fellow of All Souls and the other Warden of Merton, the two Colleges of which the Archbishop of Canterbury was always Visitor.

They were all thankful the Archbishop went on that medicine could now turn from salvaging the wreckage of fratricidal war to peaceful and constructive tasks. The medical profession had always been governed and disciplined by the zeal for scientific truth, the passion to serve society, and the sense of personal vocation. Although we expect the members of the medical profession to know their job scientifically and to serve the public well and skilfully, what in the end we treasure most about them is something in their character which is the proof of their personal vocation and devotion and we all pray that that may never grow less in this great profession.

MR. ERNEST BEVIN, the Foreign Secretary, who also responded, said that this was not his first experience of the College. He had attended an earlier dinner in which he had ventured to ask for the help of the members of the College in industrial health and welfare, and he expressed his appreciation of the progress made in that field, although it was not so much as he would have liked. He also referred to the work done by the joint committee of the Trades Union Congress and the British Medical Association, which he thought had done a great deal to bring the medical profession nearer to men and women at their work. A tragic shortage of efficient manpower would

exist in this country for several years to come. This was due to two causes—the losses of the last war, which were now being felt in the scarcity of responsible men between the ages of 45 and 55, and the losses of this war, as measured not only in life but in interruption of training. The devastation in Central Europe, the loss of productive capacity all over the world, the tremendous wealth of the United States, the enormous power of Russia, all made it evident in different ways what a great burden was laid upon the British people if British leadership was to be maintained. During the next twenty-five years they could not afford to lose a single productive unit. "I know that you as one of the great professions will cast aside any prejudices you may have, and just as you flung everything on the altar to resist the enemy, you will place your great ability to the fullest extent to the common service in order that this country may survive and still play its part in human destiny."

RHEUMATIC FEVER AND HEART DISEASE

The annual Harveian Oration founded by William Harvey in 1656 was delivered on Oct. 19 at the Royal College of Physicians of London by Dr. JOHN PARKINSON, physician to the cardiac department of the London Hospital and to the National Heart Hospital.

Dr. Parkinson said that Harvey, by his discovery of the circulation, confined to the blood and the blood vessels the evil humours of early writers which were regarded as the cause of rheumatism. In the 17th century rheumatism was differentiated from gout; in the 18th century rheumatism was first recognized as being associated with the heart, and in the 19th century this association was confirmed.

Rheumatic fever of childhood was the main source of heart disease up to the age of 40. The damage was done between the ages of 5 and 15, and it exceeded tuberculosis as a cause of death to the age of 20. During this war, as in the last, large numbers of our young men were found unfitted for service because of valvular disease of the heart directly due to juvenile rheumatism. It was estimated that almost one-tenth of all rejections were on account of heart disease. In peacetime the economic loss each year could be judged by the fact that the duration of economic activity in these men was no more than ten years on the average. All were agreed that poverty and overcrowding were basic causes, and rheumatic fever was rare among children of the well-to-do. Anything a Government did in these directions would reduce the incidence of rheumatic heart disease.

Dr. Parkinson said there was almost unanimous opinion that compulsory notification of rheumatic fever was essential to progress, for it would permit its early diagnosis before heart disease had taken hold. The excellent scheme for rheumatic fever now in operation by the London County Council was copied in the United States and elsewhere as the most comprehensive in existence; but doctors knew, and the public should know, that institutional treatment from the outset, and subsequent supervision, would have to be extended to every case of rheumatic fever occurring in this country. There should now be created a Rheumatic Fever Committee to co-ordinate research and plan for the future. The Orator believed that the Royal College of Physicians was prepared to take a lead in this great endeavour. The objective should include one main country hospital for research, and hospitals and clinics to serve all densely populated areas. Ultimately it would be found necessary, as it had been in the United States, to create a National Council for Rheumatic Fever and Heart Disease.

HEBERDEN SOCIETY MEETING

The Heberden Society will begin its first post-war academic year with a two-day meeting in London on Friday and Saturday, Nov. 2 and 3. This clinical and scientific society, founded in 1936 for the advancement of the study of rheumatic diseases, and closely associated with the Empire Rheumatism Council, has been so re-organized that membership is now drawn from all centres in the British Isles, notably the universities and spas. The inaugural general meeting, which is timed to coincide with part of the post-graduate course arranged by the Empire Rheumatism Council (see *Journal*, Oct. 13, p. 516), opens on Nov. 2 in the rehabilitation unit

of the Royal Free Hospital at 4 p.m., when during tea there will be exhibits. A short business meeting will be followed at 4.45 p.m. by a lecture-demonstration on recent advances in physical methods by Dr. C. B. Heald in collaboration with Fl. Lieut. B. C. Elliott, Dr. Graham Weddell, and Sister F. L. Greenhill. (Medical practitioners attending will be welcomed to tea, provided they apply for a tea invitation to Miss Bereton, 91, Priory Road, West Hampstead, N.W.6.) On the same evening the members will dine at the Euston Hotel. On Nov. 3 at 10 a.m. at the Middlesex Hospital Prof. B. Windeyer will give a lecture-demonstration on the treatment of ankylosing spondylitis by x rays.

BRITISH CIVILIANS RELEASED IN CHINA

We have received from the War Organization of the British Red Cross Society and Order of St. John of Jerusalem a preliminary report—dated Sept. 11, 1945, Shanghai—on the British inmates of civil assembly centres. The author is Dr. W. S. Flowers, the War Organization's medical superintendent in China.

Health of the Inmates

The physical condition of the 5,570 internees in the several internment camps is surprisingly good. Despite crowded living conditions, some deficiencies in diet, and inefficient and uncertain sanitation (which in Ash Camp was found to be both primitive and inadequate), no serious epidemic diseases have broken out. There has been a good deal of malaria, particularly in Lungghwa Camp, where a very unreliable water supply could be maintained only with much labour and worry, and where 45% of the internees had one or more attacks of malaria. Yangtzepoo Camp has had a mild epidemic of amoebic dysentery, while all camps have had dysenteric diarrhoea. One camp had an epidemic of whooping-cough which affected most of the children. There have been recently a few sporadic cases of encephalitis japonica, from which the mortality among the stateless outside the camp has been as high as 75% but has not so seriously affected the internees in Allied camps. Otherwise the physical condition of the people, including the children, has been well maintained. This has been largely due to the untiring labours, vigilance, and medical nursing care provided by a fine team of doctors and nurses in each camp, and dental facilities were made possible by a good team of dentists. Equipment was limited and supplies were often short, but by improvisation and local purchases an amazing medical service was developed and maintained.

The figures under a rough-and-ready classification are as follows: Ash Camp, 424 persons; Yangtzepoo, 1,122; Pootung, 881. Lungghwa, 1,538; Chapei, 703; Lincoln Avenue, 295. Up to the present we have no report from Yangchow (total 607), but anticipate that the internees there will be in equally good health.

While the physical condition of these people is good, they are all obviously very tired, many have lost a good deal of weight, the majority are definitely anaemic, and all are eager to escape from "camp life" as early as possible. The camp mind and outlook is psychologically interesting: memory is unreliable, and outlook and interests have been narrowed. The mortality has been low—if anything lower than it would have been had these people been living the normal rushed life of civilization. The majority of deaths have been among the aged from natural causes. There has been no typhus, typhoid, or cholera.

Nutrition, Housing, and Recreation

Nutrition has varied considerably from week to week. The average level was above 1,700 calories per head. Occasionally it fell below this as a punishment for escapes or attempted escapes. Fats were not very plentiful, milk for the children was always in short supply—generally about 6 oz. could be allowed daily to them. Adults often went short to maintain the best standard possible for the young, who are uniformly in pretty good shape. Detailed charts of the nutrition show peak periods when parcels came in and low periods when punishment was meted out. Recent liberal supplies from United States sources have adequately supplemented all previous deficiencies. Vitamin extracts have generally been sufficient to make up for other shortages.

The accommodation provided allowed 40 sq. ft. per person. The barrack-like buildings which were converted into dormitories allowed of little privacy, only curtains dividing the families. For the large majority there was obviously no escape from the crowd by day or night. Most places had room for some recreation, but Jap guards prevented any wandering over the fences. They would not allow the preventive units formed to wander into the paddy fields to prevent the breeding of the mosquitoes responsible for so much malaria. Sanitation was rarely very good, and only by the labours of the internees themselves was some hygiene maintained. The kitchens where they worked in shifts for the cooking of their own food were very primitive and must have demanded incessant effort to keep clean. Water supply, except at the Lungghwa camp, was generally good.

Recreation fields were laid out where there was room by their own labours. Football and tennis were possible part of the year. Exercise was practised by all at first, but towards the end few had energy for it. Schools for the children were run in the camp by a band of teachers and the children sat their exams even up to matriculation. Lectures, concerts, plays and opera filled in the evenings, and there were few signs of boredom. It all represents a refusal to be hindered by circumstances from pursuing a free and enjoyable life.

Summary

The health record is good. All are tired, many are anaemic, and many are affected to a greater or less degree by psychological changes. Conditions were favourable for large epidemics, but none developed.

Malaria could not be prevented in view of Japanese control, but was adequately treated. Morale was maintained throughout, despite the mixed community assembled together in such close proximity and lacking all privacy, by the efforts of enthusiastic leaders, teachers, and entertainers.

Reports of Societies

INTERNATIONAL BIOLOGICAL STANDARDS

DIXON MEMORIAL LECTURE BY SIR PERCIVAL HARTLEY

The Walter Ernest Dixon Memorial Lecture was delivered in the Section of Experimental Medicine and Therapeutics of the Royal Society of Medicine on Oct 9 by Sir PERCIVAL HARTLEY, Director of Biological Standards, Medical Research Council. Dr E H ALLOTT presided.

After a tribute to Dixon, one of the earliest advocates of the biological standardization of drugs Sir Percival described a biological standard in its simplest form as an arbitrarily chosen but representative sample of the substance for which it was to serve as a basis of measurement, preserved under conditions ensuring its permanence. A unit might be defined as the specific biological activity contained in a certain weight of the standard. The first biological standard to be established was for diphtheria antitoxin, the discovery of which by von Behring was announced in 1890. Then followed Ehrlich's remarkable series of researches, amongst the most famous in immunology, which laid the foundation of biological standardization as it was known to-day. The supply of standard diphtheria antitoxin from Ehrlich's institute at Frankfurt ceased with the outbreak of war in 1914, and this withdrawal rapidly led to the establishment of the standard on an international basis and to the creation and adoption of international standards for other substances.

In 1921 an international conference in London recommended the adoption of Ehrlich's original unit as the international unit, and in the following year a second international conference in Paris explored the possibility of establishing standards and units for other antitoxin and antisera. As an outcome of this and later conferences international standards for digitalis, pituitary (posterior lobe) extract, insulin, and the arsphenamines were adopted, and a Permanent Commission on Biological Standardization was set up by the Health Organization of the League of Nations to provide international standards and units and to secure their widest acceptance. Within less than twenty-five years 35 international biological standards had been established, and even during the recent war progress had not stopped, for standards for vitamin E (1941) heparin (1942), and penicillin (1944) had been adopted during that period.

International Achievement

The materials for biological standards had come from many countries but in all but seven of them the final operations to secure conditions of permanence and stability had been carried out in England and for all but two of these at the National Institute for Medical Research, Hampstead. Five of the original international serum standards were made at Hampstead, and a number of equivalent international standards had also been made there for the purposes of the Therapeutic Substances Act and the *British Pharmacopoeia*. To illustrate the international character of the work, the lecturer mentioned that material for the serological standards was supplied from England, Denmark, and the United States, the tuberculin standard was made in England, material for the vitamin

standards came from Switzerland, Dutch East Indies, Hungary, England, France, Germany, Sweden, and the United States; that for the arsphenamines originally from Germany and the United States and later from England; the first insulin standard was made in England and the second in Canada, the material for both pituitary (posterior lobe) standards was supplied from the United States and manipulated in England, the first digitalis standard was prepared in Holland, the second in England, ouabain standard material was supplied from France, materials for the sex hormones were supplied from eight countries, Canada provided the material for the heparin standard and the United States and this country the material for penicillin.

Practically all the material for these standards was presented to the international organization some of these gifts representing very large sums of money. A laboratory in Switzerland presented 30 grammes of androsterone to provide the replacement standard for male hormone activity; a laboratory in England presented 20 grammes of the purest beta-carotene to provide a replacement standard for vitamin A and another presented 30 grammes of pure crystalline penicillin sodium salt for the standardization work in Hampstead. Free distribution was made of all standards issued from Hampstead on a national basis or to the British Commonwealth or to individual research workers anywhere, as for the international standards.

Standard for Penicillin

After recounting the course of events which led to the adoption of international standards for vitamins and the subsequent action in this field Sir Percival Hartley turned to the latest standard, possibly the last, established by the Permanent Commission—namely, the international standard for penicillin. For many reasons, he said it was desirable that an international standard for penicillin and an international unit defined in terms of it should be agreed and established without delay. Delegates from five countries with expert observers from certain others met in London a year ago under the chairmanship of Sir Henry Dale and unanimously recommended the adoption of a sample of pure sodium salt of penicillin II as the international standard, and for practical reasons which were justified at the time a sample of a calcium salt of penicillin as the international working standard. The international unit was defined as 0.6 microgramme of the international standard and such unit was contained in 2.7 microgrammes of the international working standard. Decisions as to nomenclature and other matters were also recorded by the conference.

Hampstead they were now almost ready for the final step of giving effect to these decisions by the world wide distribution of penicillin standards. He exhibited a sample of the international standard mentioning that at Hampstead they had over 300 such small containers, each holding about 30 microgrammes, also a sample of the international working standard of which they had 200 containers each containing about 65 milligrammes. The actual international standard preparations obviously could not be used for the routine assays of penicillin, there were not enough of them, but they were supplied for the assay and periodical check up of equivalent national standards which the national control centre of each country was expected to prepare.

The Oxford Unit

The first standard for penicillin was made at Oxford and the unit of activity, which came to be known as the Oxford unit, was defined as that which was contained in 0.23 milligramme of this preparation. In one way or another the original Oxford unit had been redetermined in many other, more active preparations. At Hampstead they were provided with two such accurately assayed preparations—one containing 71 and the other 84 units per milligramme—and with these the potency of the British standard for penicillin—155 units per milligramme—was assayed. These three preparations, with two others from the United States carrying the Oxford unit, were included in the samples examined by the London conference a year ago. The results of the assays, despite the different methods employed by the collaborating laboratories showed remarkably good agreement. There was sound evidence that the value of the unit which was being used a year ago in the United States was the same as the value of the unit being used in this country, from which it certainly seemed that, in

spite of the repeated redefinition of the unit in both countries, the original value as defined at Oxford had not been significantly varied. Finally, the value of the unit recommended for international adoption was approximately equivalent to that originally adopted at Oxford.

Impending Developments

Sir Percival then discussed the important part which international biological standards had played in ensuring the high quality of therapeutic substances. The Therapeutic Substances Act had for nearly 20 years controlled the supply of certain drugs and medicaments, but it was limited in scope and in geographical application. For example, its control did not extend to the vitamins or heart drugs, and its application was restricted to Great Britain and Northern Ireland. A way had been found, however, whereby both these limitations might be overcome—namely, by including all the substances for which international biological standards had been established in the *British Pharmacopoeia*, and the *Pharmacopoeia* on its part had laid down the principle that the standards and units to which pharmacopoeial preparations must conform were the international biological standards and units. In some parts of the British Commonwealth and Empire a control over these substances similar to our own had been established, and in these countries also international standards were in general use.

After describing the interesting replacement operations which had taken place from time to time in respect of 18 of the 35 standards, including the first insulin standard and the first standards for pituitary (posterior lobe) extract and for vitamin B₁₂, the lecturer said it was quite likely that a new international organization which might replace the Permanent Commission of the League of Nations would decide that standards for antisera and some of the antitoxins could be dispensed with, and that arsphenamine—the original “606”—had earned an honourable retirement. The position of vitamin standards might also come under review. As Sir Henry Dale had picturesquely put it, “The ultimate aim of biological standardization, as of all preventive medicine, may be regarded as self-extinction.” But there were new candidates with good claims to admission. The standardization of the diphtheria prophylactics was a problem of outstanding importance and urgency. The establishment of an international standard for tetanus toxoid for the active immunization of man might well have an early priority. Some of the investigations carried out at Hampstead regarding the standards for and the assay of gangrene antitoxins, which became urgent and important because of the immediate needs of the war, also indicated new directions in which the work of biological standards might develop.

International biological standards might find useful application in the rapidly developing field of chemotherapy. Pure substances could, as a rule, be fully described in chemical and physical terms, the doses to be administered could be expressed in weight, and biological standards and units were neither necessary nor desirable. It was otherwise, however, in the case of substances of proved biological activity and clinical usefulness of which the chemical composition was unknown, and successive batches of which possibly exhibited varying biological properties. For such substances, in the interim period pending the discovery of their chemical composition and structure, or perhaps of a more reliable process of manufacture, experience had shown the value of the adoption of a standard by comparison with which other preparations could be matched.

THE “DISCHARGING LESION” IN NEUROLOGY

At a meeting of the Neurological Section of the Royal Society of Medicine on Oct. 4 the new president, Dr. J. Purdon Martin, delivered a presidential address on the subject of the “discharging lesion” in neurology.

The theory of the “discharging lesion” was propounded by Hughlings Jackson to account for convulsive phenomena, but Dr. Martin considered that it was capable of a wider application in neurology than had hitherto been accorded to it. The theory postulated that nervous tissue (and therefore nerve cells, inclusive of their axis cylinders) “stored up” energy, and under

the influence of physiological stimuli some of this energy was emitted in an orderly and controlled manner as impulses, but that under certain abnormal conditions the energy might be discharged without a physiological stimulus, and then in an excessive, uncontrolled, and disorderly fashion. A portion of nervous tissue which was in a pathological state such that was liable to discharge in this manner constituted a “discharging lesion.” Modern physiological knowledge lent much support to this theory, and he (Dr. Martin) had in fact come to it chief by way of the physiology of muscle.

Jackson was mostly occupied with convulsions, but there were many other phenomena which provided objective evidence of “uncontrolled” and apparently unphysiological discharge (some of which Jackson had referred to in his writing). Observation led to the belief that discharges might be of three different degrees or varieties, which, however, graded into each other. The convulsion was evidence of a massive or explosive discharge. The smaller repeated discharges which would give rise to peripheral facial spasm, or to the muscular fibrillation of amyotrophic lateral sclerosis, might be described as “spluttering,” while those that caused continuous spasm of muscles such as trismus might be called “continuous.” There was evidence of a still lesser degree of abnormal instability in certain conditions in which there seemed to be an excessive motor response to normal stimuli, as in some of the motor phenomena of tetany and of tetanus and of strychnine poisoning.

Jackson considered that symptoms attributable to “spontaneous” discharge were essentially paroxysmal and transient, since the portion of nervous tissue from which the “primary” discharge occurred required time to become again “overcharged.” While it was true that the phenomena indicative of massive discharge were transient, those attributable to “spluttering” and “continuous” discharges might go on for a long time, and in some instances for the rest of the patient's life. Trismus and tetany were actually continuous, while peripheral facial spasm might be said to be paroxysmally continuous. In regard to all of these we must suppose that in the discharging nervous elements the store of energy on which the discharge depended was being renewed as quickly as it was expended. A similar condition of energy exchange could be maintained and demonstrated in muscle, and was known as a “steady state.” The peripheral facial spasm which occurred as a sequel of Bell's palsy was associated with an imperfectly recovered nerve. The fibrillation of amyotrophic lateral sclerosis was associated with a degenerative state of the anterior horn cells.

We might apply, Dr. Martin continued, what we have deduced from observation of the motor phenomena to the interpretation of certain sensory phenomena which patients described. After a vascular lesion of the thalamus, imperfectly recovered cells of the “pain system” might constitute a discharging lesion and achieve a steady state, thus giving rise to the spontaneous pain of continuous nature that was the characteristic after effect of such a lesion. In other cases the degree of recovery might be such that the cells did not discharge spontaneously but their “energy substance” remained hyperexcitable (e.g., in consequence of anoxia) so that they reacted excessively to normal stimuli. The alternative theory—that the “thalamus syndrome” resulted from a release of the thalamus from control normally exerted over it by the cerebral cortex—was not in keeping with some of the essential facts.

In the case of a recovering sensory nerve (as in that of the recovering facial nerve) there might be a state of instability of the energy substance, and this might be the basis of that hyperalgesia which Head attributed to “protopathic sensation.”

Lightning pains in tabes were attributed to discharges occurring in degenerating afferent elements. If a discharge arose in the afferent portion of a reflex arc it might give rise to reflex movements. All the organs liable to be affected by visceral crises were reflexly controlled, and such a crisis might be due to “spluttering” discharges in the afferent part of the arc producing the effect of an irritant or foreign body in the viscera concerned.

All these symptoms had something in common—namely, an excessive, “explosive,” or compelling quality. The motor phenomena referred to had also this in common—that they might occur or continue during sleep. This applied to convulsions, facial spasm, tetanus, and tetany—whereas motor

abnormal movements, such as those of paralysis agitans, chorea, and spasmodic torticollis, ceased during sleep. This difference might not be fundamental, because chorea had many of the features of a symptom due to "spontaneous" discharges.

The theory provided explanations for, and enabled one to see a certain unity in a number of symptoms for which the current explanations were unsatisfactory. Dr. Martin recalled a quotation from Pasteur: "... the characteristic of a true theory is its fruitfulness."

Correspondence

Telling the Patient

SIR.—Major J. C. Hogarth's letter on this subject (Oct. 13, p. 513) is timely and deserves more than a passing comment. Observations of the same kind have been made to me by a number of thoughtful Service medical officers—usually with unit experience—who have been frankly shocked by the impersonal methods which prevail in many Service and E.M.S. hospitals. I had frequent occasion to make similar criticisms, during the first three years of the war, as the result of my numerous contacts with E.M.S. and teaching hospital medicine.

How have these strange habits of thought and action, this routine of intensive and often repeated investigation and multiple specialist opinions, but with so little said and done for the patient as a person, come to characterize hospital practice? What is the function of the physician, what is the object of medicine if it is not to help the patient's mind and body in every way possible and at every stage of his illness? There can be no greater disservice than to leave him puzzled or in the dark. It is a sad reflection on the trends of our clinical teaching in recent decades that institutional medicine should now so frequently be allowed to degenerate into a kind of mechanical bedside pathology; that it should prefer reports and labels to human histories, and diagnoses and treatments to "treatment," and delight so selectively in what is called the "interesting" case. "Examination, explanation, and reassurance" should be as much in the mind of the student and young doctor as "inspection, palpation, percussion, and auscultation," if—that is to say—he cannot be human without a mnemonic.

In another letter in the same issue Wing Cmdr. Bergin comments on some of the consequences of the modern "passed to you, please" ritual of investigating and handling patients. What a travesty of our old clinical discipline it is to employ a succession of specialists to exclude organic disease and then to ask a psychiatrist to make the final diagnosis, and, too often, to confirm the invalidism. The technological age in medicine has added much to our investigatory powers and has done much for many patients, but it is time our science and humanism resumed a more equal co-partnership. Two books have recently been sent to me from the United States, where similar trends are, I gather, all too common. One is called *The Patient as a Person* (by G. Canby Robinson), the other *Patient as Families* (by Henry B. Richardson). We stand on the threshold of large reforms in our teaching and our practice. May we hope that the teachers of the new generation will take every occasion to remind their students and house-officers that "patients" are, above all, "persons" and not just "cases," and also that they have families and that they get better more quickly or accept their adversities better if they and their families are simply and clearly told what they most need to know?—I am, etc.

Oxford

JOHN A. RYLE.

SIR.—How cordially I agree with Major Hogarth's suggestion that the patient be given constructive information about his complaint. I would go further, and suggest that therapy is incomplete until the disease is evaluated to him in terms commensurate with his intelligence, education, and emotional maturity, and until he is helped to adjust to it.

One of my first lessons in psychotherapy—from Dr. T. A. Ross; I have never forgotten his advice—was that the patient should be completely overhauled physically and the nature of his physical complaints precisely delimited and evaluated to him. How much more important, surely, where the complaint

is predominantly physical; or in the extending field of the psychosomatic complaint—i.e., the physical symptom due to emotional stress.

Hypochondriasis is due to—or at any rate encouraged by—ignorance or fractional knowledge. It is surely the function of the doctor—specialist or G.P.—to dispel that ignorance. In doing so he will tend to clarify his own clinical conceptions and amplify his own therapeutic influence, by failing to do so he may become the creator of suffering. In doing so he will also help dispel the suspicion—explicit in many intelligent laymen and implicit in many more of their less articulate brothers—that much of the doctor's business is a defensive juggery-pokery of false magic.

The doctor who has not the patient's full trust is crippling his own therapeutic influence. That trust can be more easily gained if a more rightful conception of the doctor's business is encouraged that his influence is based, not on symbols, prestige-attitudes or an implicit claim to a higher esoteric level of understanding, but on compassion fused with skill and experience and the ability to help the patient to see his complaints in their proper perspective.

Much avoidable psychotherapy, suffering, and distrust of the medical profession could be prevented if more doctors—specialist or G.P.—were to spend the few moments necessary to complete their therapeutic effort by bringing the patient into the picture. It would also help those of us who come later to get a reasonable medical history. I am continually being surprised by the number of intelligent young officers who have vague ideas about quite serious illnesses and who are naturally worried because no one has told them what to expect or what to do about it—I am, etc.

H. HARRIS,
Lieut. R.A.M.C.

Witley, Surrey

SIR.—Major J. C. Hogarth (Oct. 13, p. 513) surely realizes that in the out-patient department of a hospital the patients are referred for an opinion by the general practitioner. The majority of these practitioners, I am sure from personal experience, would resent the out-patient physician discussing in detail the diagnosis, prognosis, and treatment with the patient. This is the function of the general practitioner, and it is the physician's duty, in my opinion, to communicate only with the doctor concerned. Only in exceptional cases and at the doctor's request should the physician discuss the diagnosis with the patient. Otherwise, surely, essential trust and harmony between patient and general practitioner are apt to be jeopardized—I am, etc.

E. IDDIS JONES.

Rehabilitation of Fractured Limbs

SIR.—The letters of Dr. R. Murray Barrow (Sept. 8, p. 332) and Dr. Vaughan Pendred (Oct. 6, p. 475) prompt me to point out that in 1899, when a student at Edinburgh University, I was transferred to Prof. Annandale and Mr. J. W. Dowden at Edinburgh Royal Infirmary an electrical method of producing controlled contractions and relaxations of any of the muscles of the body. With their assistance I treated various types of fractures, particularly Colles' fractures, the latter being put in plaster and the case split in four to eight days, then daily contractions of the extensor and flexor muscles were produced by the apparatus described, so as to cause movements of the wrist and fingers. I showed that contractions and relaxations were so finely controlled that only the slightest movements of the muscles were discernible at first, and gradually increased to the maximum required without pain until the wrist and fingers were put through their full range of movements. About the year 1905, when I was in charge of the X-ray Department of Great Ormond Street Children's Hospital (which I started as a department), I showed the same method to Sir Arbuthnot Lane and Mr. Stansfield Collier, who were so impressed with the results that they sent many of their fractures to me for treatment by this method. In spite of the recent literature advocating long periods in plaster I have continued to carry out this method with consistent success, and full functional use of the wrist is obtained in much shorter time than when treated by the present-day so-called orthodox method.

By the method I advocate, which has stood the test for so many years, an important factor is that the muscles can be

made to contract and relax painlessly *without their point of origin being approximated*, so that considerable movement of muscles in the initial stage of treatment can be carried out without moving the fractured ends of the bone in the slightest degree. This reproduction of the function of the muscles in the neighbourhood of a fractured bone by graduated contractions acts beneficially in the following manner: (1) The contractions and relaxations gradually increase the local blood supply and aid its circulation, so that absorption of lymph and extravasated blood in the tissues is rapidly promoted and the growth of callous powerfully stimulated. (2) Slight movement at the broken ends may increase the production of granulation tissue by causing hyperaemia. (3) The movement of the muscles prevents contiguous muscles, tendons, and other structures from becoming adherent. (4) The reproduction of the physiological action of the muscle prevents their becoming atrophied. (5) By the muscle movements increasing the local blood supply, the resting bone is less likely to become atrophied. (6) By preventing adhesions and wasting of muscles, as soon as the repair of the bone is sufficiently advanced, the patient is able to regain full function in the limbs very much sooner than is possible where adhesions and wasting of the muscles result from enforced complete rest.

I can claim for this method that, if properly carried out, there is no danger and that the results in time and restoration of function are most satisfactory.—I am, etc.,

London, W.1.

MORTON SMART.

Sciatic "Neuritis"

SIR,—Dr. J. MacDonald Holmes and Mr. B. R. Sworn's article on sciatic neuritis (Sept. 15, p. 350) will be of great interest to all who have to try to deal with the problem of sciatic pain. But I still think that an injured intervertebral disk might account for their cases, both of which gave a history of associated trauma, for what that is worth. It is possible to envisage injury to the attachment of part of the annulus fibrosus, allowing a local bulging of the disk in the standing position which would be absent in the position at operation, and where no softening or break in the posterior contour of the annulus would be felt. I am uncomfortably aware that this explanation is highly suppositive. But I feel we should be unwilling to abandon a pathological concept which has shed so much light on sciatic pain, unless logic truly demands it.

Symptomatic relief from decompression is understandable with any pathology. But if the disk is damaged, further protrusion in the years to come might be expected. It will be interesting to know if either symptoms recur as the protrusion again fills up the extra space provided, or a demonstrable narrowing of the disk space occurs.—I am, etc.,

C. W. M. WHITTY,
Major, R.A.M.C.

Psychiatry in the Services

SIR,—As a practising psychiatrist it is with much regret that I find myself in agreement with most of the statements in Wing Cmdr. K. G. Bergin's letter (Oct. 13, p. 508); for, having myself served as a unit medical officer, I realize that there is no lack of confirmatory evidence regarding the facts mentioned. I have no doubt that the majority of unit medical officers could cite an infinite number of similar cases, and I am sure that many other correspondents will be only too glad to recall their own experiences. Personally, however, I am much more concerned in striking at the root of the trouble, and, though willing to admit that there are many first-class psychiatrists serving in the Forces, I do not agree with Wing Cmdr. Bergin's statement that the psychiatric branch can be exonerated from all blame in the matter of the treatment and disposal of such cases. It must be admitted that, owing to the shortage of trained psychiatrists, it was inevitable that the original selection of personnel for this branch was a matter of great difficulty, and, for the same reason, it was impossible to give these officers an adequate military training. It is, indeed, a well-known fact that, especially in the early part of the war, many "specialists" were appointed though there was scant evidence that they possessed more than a superficial knowledge of their "specialty."

In my opinion many of the difficulties confronting even the expert neuropsychiatrist would have been obviated if these

specialists had been posted for an adequate period as ordinary unit medical officers. They would then realize to the full the actual conditions under which Service personnel—especially N.C.O.s and other ranks—live and work. This, I believe, is the crux of the whole problem, and raises a matter which is of vital importance to the future of psychiatry. Although he is obviously viewing the matter from an entirely different aspect, I think that Wing Cmdr. Bergin sums up the situation very concisely in the clause: "... a system which lays too much stress on psychological illness and not enough on a man's responsibility to his fellows." It is obvious that he did not intend this to be an indictment against psychiatry, but we who profess to be psychiatrists would do well to ponder and give the matter much consideration. In the past too much stress has been laid on the academic and scientific aspects of psychological medicine, and the sociological implications have not received the attention they deserve. This broader view can be achieved only when psychiatry is accepted as an integral part of the social service of the community and not segregated as a little-understood and narrow specialty.—I am, etc.,

St. James Mental Hospital,
Milton, Portsmouth.

W. LIDDELL MILLIGAN.

SIR,—Wing Cmdr. K. G. Bergin's experience (Oct. 13, p. 508) differs entirely from that of all serious writers on the subject of Service neurotics in two respects—their progress after invaliding and their response to disciplinary measures. Careful follow-ups on patients who had been invalided out of the Services for neurosis were done by Lewis (*Lancet*, 1943, 1, 167) and Ferguson (*Health and Industrial Efficiency*, H.M.S.O., 1943), it being found that the great majority were still seriously incapacitated after months of civilian life. I have encountered many patients of this type who had been harshly dealt with by the executive because of their failure to meet the demands made upon them or their supposedly malingering propensities. In each case the results were disastrous, and a completely useless individual, often with a very great nuisance value, was produced. Such eminent psychiatrists as Ebaugh (*Manual of Military Psychiatry*, W. B. Saunders, Philadelphia, 1944) on the other side of the Atlantic and Hadfield (*British Medical Journal*, 1942, 1, 281) on this have emphasized the unfortunate consequences of treating these patients as malingerers. "Neurotic symptoms are very real, and the man or woman in a state of pathological anxiety and depression finds it more difficult to lead a normal active life than does a healthy person. A refusal to recognize this produces a strong sense of injustice and grievance and has a most harmful influence."

That the object of neurotic behaviour is to procure discharge from the Service is a dangerous half-truth in so far as it implies that this is the chief or sole *raison d'être* of the illness, and that it will cease as soon as it is made quite clear that there is no chance of this end being achieved. In fact the genesis of these states is complicated in the extreme, and in most cases the neurotic behaviour cannot be stopped by any method known to man.

Wing Cmdr. Bergin's examples are completely unconvincing and indicative of a disarmingly naïve outlook. For example, the ability to cycle home and work in the garden with every appearance of pleasure does not in any way suggest that the man's distress when required to work overtime is feigned or exaggerated.

It is obvious that Wing Cmdr. Bergin has let his judgment and interpretation of the facts be influenced by his moral indignation at the gain which the neurotic may derive from his illness. This gain is a common phenomenon in civilian life also and by no means confined to conditions of military conscription. The only way to prevent this secondary gain in the circumstances would be to gather the neurotics into special units, which would probably serve little useful military purpose and whose chief function would be to keep the personnel on Service pay and living under camp or barrack conditions, so satisfying the code of morality which Wing Cmdr. Bergin advances and which will command widespread approval. These units would require efficient administrative staffs, which would be hardly justifiable from the point of view of the national interest in time of war. The "system" which is castigated is presumably that of invaliding on medical grounds for neurosis. From the moral point of view there is much to be said for the

merican system of discharge on the grounds of inaptitude. Not that I personally would agree that our present system is immoral.

The grossly unsatisfactory state of the treatment of neurosis at the present time arises out of the stubborn and intractable nature of these pathological emotional disturbances. Light-hearted superficialities will not help in the solution of this problem—I am, etc.

Chichester

A. HARRIS, S/Ldr.

SIR,—I have read Wing Cmdr. Bergin's letter, and there is no doubt that his remarks are only too true. It has been my unfortunate lot as a station medical officer to have to deal with a vast number of these cases, and his description and subsequent history are correct in every detail. Many station medical officers with whom I have discussed this type of case are agreed that the approach and handling are wrong, but unfortunately they have no other way of dealing with them. The solution suggested by Wing Cmdr. Bergin—i.e., Do your duty or take the consequence—is of course the solution to the whole problem; but unfortunately it is not so easy as that. I have tried that myself successfully on occasions; but from time to time political influence has been used and instructions issued from higher authority that the patient is to be dealt with in a certain manner. These instructions are issued by someone who has never seen or examined the patient and without consulting the station medical officer. After much thought I have come to the conclusion that the vast majority of these patients are devoid of all sense of duty and are sickened only by selfish thoughts.

The only solution is courage—courage on the part of the medical branch to stand by their convictions; courage among the higher authorities to stand by the medical branch and to say so publicly; and, lastly, courage in the hearts of the weak and selfish to face the slings and arrows—I am etc.,

G. F. MAGURRAN

SIR,—Wing Cmdr. Bergin seems to be passing through one of the phases common to medical officers. Even the kindest M.O. is apt to feel annoyed when he discovers what he fancies is a leg-pull, and he naturally relieves his feelings by a more or less indiscriminate outburst of severity, rationalized in whatever way appeals to him. A few M.O.s become congealed in this phase, or its opposite extreme of leniency, but the majority gradually settle down to a middle course as they grow more able to discriminate and less afraid of being wrong. It is perhaps better to be fooled occasionally than to be unjust to an honest man. Even the irritation of being informed—with relish—by a non-medical officer that a man for whose story one has fallen has been heard boasting of his successful deception may be soothed by the reflection that this is by no means proof of malingering.

As to the methods in vogue for separating the wheat from the tare, they fall into three classes: (1) "The Sign from Heaven," otherwise known as clinical intuition or diagnostic acumen. (2) "The Geographical." Certain parts of the British Isles seem to maintain steady streams of "bad eggs" to the Services. Wild horses would not induce me to name my own favourite black spots. (3) "The Police Method," which relies on "information received" and on catching the accused out in contradictory statements.

By a judicious combination of these methods supplemented by very occasional disciplinary action, it should be possible to keep the lead-swinging rate within reasonable limits. The picture that Wing Cmdr. Bergin paints of neurotics "almost without exception" deteriorating steadily and being invalided out is quite outside my experience in the Army. It certainly need not happen, and if it does it must be—in spite of his statement to the contrary—the fault of psychiatrists, unit medical officers, or the executive.

The moral issue, to which your correspondent refers, is simple enough in theory. The measure of a man's sacrifice is the degree to which he disliked making it. War divides people into those who like it and those who don't. Those who like it go willingly, knowing the risks and discomforts; they are the lucky ones, and they have their reward. They make the best soldiers, of course, but to be quite fair they should clearly not be allowed to get away with it; if fairness were the only

consideration, they would sternly be directed into offices, factories, or other occupations uncongenial to them, so long as other people are forced into the Army against their will. Fairness, however, must come second to efficiency, and even if it did not it would be impossible to be fair to everybody. And since we cannot claim to be fair, it is difficult to see how we can demand "duty" and "moral responsibility." Such words have their cynical uses, of course. But we live to be fair in our thoughts even if we cannot be fair in our actions (at least, we think we like to), and we cannot be so unless we realize that the man whose dislike of service is sufficient to drive him to decisive action, whether that action take the form of desertion, malingering, or the development of neurotic symptoms is getting, or has had, a raw deal by comparison with his better-adapted comrade. This is no place to enter into futile arguments as to who suffers most—the man who protests or the man who would like to but doesn't. Sufficient has been said to make it clear that moral superiority is not an attitude which becomes us.

The system of which Wing Cmdr. Bergin complains is not intended to encourage escape, but it does recognize the essential pig-headedness of human nature. At a certain point unwillingness converges to inability, for practical purposes, and it pays better to take what the man will give rather than break him because he will not give you all you want.—I am, etc.,

Cambridge

W. E. HICK

SIR,—I have been reading with interest Wing Cmdr. Bergin's letter. The cases in which he thinks he has failed in that by their "unconscious deception" they have got themselves discharged from the Service are in my opinion his most brilliant results, in that the square pegs have found for themselves the square holes for which by temperament and capabilities they are evidently suited. No work, I think, approaches in quality that which is done happily, with interest, with vim, and from free choice. Disgruntled workers are a potent cause of accidents, in that their minds are upon themselves and their grievances rather than upon their work, and thus attention may be lacking at a vital moment.

I cannot emphasize too strongly the misery I have seen caused by labour direction to unsuitable jobs. One girl I know of went out of her mind through being directed away from her home as a mobile worker, which would never have happened if she had been left quietly alone in her factory job (which was turning out war material) in her familiar surroundings. In another case a man used to an open-air life was directed to coal-mining. When I saw him he was a miserable nervous wreck. This state was due to his being coerced into uncongenial employment, and secondly, to his having seen an accident underground whereby two men were killed.

The tragedy of this war has been that men were forced into occupations for which they were never suited by either temperament or capabilities, and their nervous reserve becoming exhausted shows this by "the well-known features, etc." which Wing Cmdr. Bergin describes in other words, the square pegs forced at the round holes, and no amount of jamming them in by harsh discipline or fear will achieve more than a makeshift fit.

There are malingerers, we all know, but these of course are in a different category.—I am, etc.,

F. M. E. DAVIES.

Anaesthetic Risks

SIR,—I have read with interest the correspondence on the advantages and disadvantages of spinal anaesthesia. In your issue of Oct. 13 (p. 511) Dr. E. Falkner Hill writes a spirited letter in its defence, but his enthusiasm has led him into making a statement which appears to me questionable. "Inhalator anaesthesia acts by interfering with and to a greater or lesser degree damaging the cerebral cells."

We know, of course, that anaesthetic procedures which deprive the cortex of oxygen for even a comparatively short time do cause permanent damage to the cerebral cells, but does Dr. Hill mean that there is "a greater or lesser degree" of damage even when the oxygen requirements are fully met? If so, it would be interesting to know what scientific ground there is for this statement.—I am, etc.,

Dunfermline, Fife

A. C. DOUGLAS

Significance of the Erythrocyte Sedimentation Rate

SIR,—Under the heading "Any Questions?" (Sept. 1, p. 307) the subject of E.S.R. has again been raised. Certain aspects of this problem were fully discussed in the correspondence which followed the paper by Della Vida (1942). In the course of a recent study we have found that confusion largely centres round the following points.

1. *Absence of a Standard Method of Performing the Test.*—Many writers do not state the method they employ. Presumably in such cases the test has been performed according to the original Westergren technique, in which 0.4 c.cm. of 3.8% sodium citrate is added to 1.6 c.cm. of venous blood. This may not necessarily be the case. For example, Dunlop and Dick (1944) employ dry potassium oxalate as an anticoagulant in what they term the Westergren method. Confusion would be avoided by describing the tests as "original Westergren" or "Westergren oxalate."

2. *Employment of Different Anticoagulants.*—Della Vida (1942) and Muller (1943) have drawn attention to the fact that the rate of sedimentation is depressed by dilution of the blood. In a recent series of cases we obtained the following results:

Number of subjects examined	18
Mean second-hour reading (original Westergren method)	22.3 mm.
Mean second-hour reading (dry ammonium and potassium oxalate method)	25.8 mm.

Although the mean value for the oxalate series is greater than that for the citrate series, individual results in the former were not uniformly greater than in the latter. Thus the results for the second hour were as follows: oxalate series greater than citrate series, 12 cases; citrate series greater than oxalate series, 5 cases; both series equal, 1 case. Muller (loc. cit.) states that results are influenced according as potassium oxalate and potassium and ammonium oxalate mixture are employed. She cites the opinion of Keen, who found that the readings obtained with potassium oxalate were accelerated and supported the clinical assessment of activity in each case examined, whereas readings with the double oxalate mixture were diminished or within normal range.

3. *Lack of a Uniform Standard of Normal Values.*—There is no agreement as to what constitutes a normal sedimentation rate, even when the same method is used. Westergren adopted the following standard for the one-hour reading: normal, 3 mm.; doubtful, 4 to 6 mm.; probably abnormal, 7 to 12 mm.; certainly pathological, 13 mm. and upwards. Most writers accept as abnormal any reading greater than 10 mm., although Young (1944) regards values as low as 3 mm. in a male and 5 mm. in a female for the first hour as abnormal. Dunlop and Dick (1944), using a 200-mm. Westergren tube and dry potassium oxalate as anticoagulant, regard as abnormal any reading greater than 5 mm. for the one-hour reading.

Disregard of Physiological Variations.—The consensus is that the only physiological state which causes an appreciable increase in acceleration is pregnancy (Muller, loc. cit.; Wintrobe, 1942), although Obermer (1943) found that some healthy women, for reasons not known, consistently show an increased rate during menstruation. A perusal of Wintrobe's figures shows that, apart from pregnancy, an appreciable number of young adults give readings above the accepted range of normality. Using a mixture of dry ammonium and potassium oxalate as anticoagulant and a 100-mm. tube Wintrobe found that the rate of sedimentation varied from 0 to 6.5 mm. at the end of an hour in 86% of 137 healthy young adult males and from 0 to 15 mm. in 88% of 100 young adult females. He found that the differences were largely accounted for by variations in the haematocrit value, and that when this was corrected to a red-cell volume of 47 c.cm. per 100 c.cm. the rate in 72% of males and females was 0 to 6 mm. and in an additional 16% 7 to 10 mm. for the one-hour reading. There still remains, however, 12% of subjects with a reading greater than 10 mm. We found that 18 of 55 (original Westergren method) and 23 of 62 (dry potassium and ammonium oxalate method) healthy hospital nurses had a one-hour reading greater than 10 mm.

In a group of schoolboys aged 14 to 15 years tested by us 5 of 37 gave a first-hour reading greater than 10 mm. (dry potassium and ammonium oxalate method). On the other hand,

among adult male subjects, only 1 of 59 (original Westergren method) and 2 of 76 (dry ammonium and potassium oxalate method) had a one-hour reading greater than 10 mm. The subjects in all these groups were apparently healthy. All had been subjected to a thorough physical examination, although not in every case, at the time the raised sedimentation rate was recorded. Skiagraphic examination of the chest was carried out in each case (on the same day as, or within a few days of, the finding of the raised sedimentation rate), and in none was any abnormality noted. Even if one accepts the hypothesis that the raised rate was due to some occult focus of sepsis, the fact remains that a considerable number of healthy subjects are liable to exhibit accelerated rates—a finding which must always be borne in mind when considered in association with abnormal skiagrams. That an appreciable number of healthy persons exhibit accelerated rates is confirmed by the work of Edwards, Penman, and Blair (1945), who found that the normal sedimentation rate in apparently healthy hospital nurses can be surprisingly rapid. They found that when primary tuberculous infection occurred the sedimentation rate increased considerably. In cases showing a satisfactory response the rate returned to the normal level for the particular subject in about a month. It would thus appear from these results that, in the female subject at least, it is necessary to learn from serial readings the physiological rate for the individual before any conclusions can be drawn from a single estimation.

The opinion is still widely held that the sedimentation rate is constantly raised in cases of active tuberculosis. Kayne, Pagel, and O'Shaughnessy (1939) and Hollins (1942) have even suggested that the test would be of value in the mass investigation of the apparently healthy. Under this arrangement only those subjects showing an elevated rate would undergo x-ray examination. Berrington and Greenwood (1942) employed this method in a mental hospital, and formed the opinion that it is rare to find active tuberculosis with a normal rate. It is difficult to understand how they arrived at this conclusion, since in their scheme active cases with a normal rate would not be examined. When the results obtained by mass radiography are studied an entirely different picture is presented, as the following table shows:

Reference	No. of Subjects with Active Tuberculosis Examined	No. with Abnormal E.S.R.
Stiehm (1933)	69	33
Braeuning (1938)	75	33
Clive (1943)	102	84
Kahan and Close (1944)	138	27
Robinson (1944)	45	35
Abeles and Pinner (1944)	91	54

It may be argued that, since tuberculous foci may undergo reactivation with considerable rapidity, it is insufficient to claim as active a case showing a normal E.S.R. merely on the strength of changes seen on serial skiagrams. Recently we had the opportunity of performing gastric lavage on the same day as, or within a few days of, the performance of the E.S.R. in seven cases. The former examination gave a positive result in each instance. The one-hour E.S.R. reading was greater than 10 mm. in three cases only, and two of these were females.

In the male subject the test may be of limited value, although the information required by the physician in assessing a case can generally be obtained more accurately without its use. Since in the female subject the test carries an error of anything from 12 to 30% its employment is, for practical purposes, valueless. No other test having an error of this magnitude would be tolerated in practice. Those seeking guidance on the E.S.R. should follow the advice of Hilliard (1942), who "abandoned the use of blood sedimentation tests long ago."—We are, etc.,

"Perspex" in Orthopaedics

SIR,—In his letter (Oct 13 p 512) Mr A. MacGowan levels a great deal of criticism against the article on perspex in orthopaedics by Scales and Herschell (Sept 29, p 423). I would suggest that he has failed to appreciate that the authors do not advocate perspex as a complete substitute for plaster-of-Paris and that they have not recommended that it should be used for short term cases, surely the list of conditions given, including tuberculosis of the spine and anterior poliomyelitis, consists entirely of those requiring many months of treatment in some form of splint.

He complains that the authors of the article do not make use of the advantages they quote, with this complaint I disagree and instance the following. In the treatment of a case of tuberculosis of the spine with or without sinuses in a young child a 'perspex' bed has the following advantages over one made of plaster-of-Paris: it can be washed without deterioration; it needs no absorbent lining; it is non-irritant to the skin, and even Mr MacGowan must concede the point that it is reclaimable; in treating cases of anterior poliomyelitis 'perspex' has the additional advantages that it is light in weight and being waterproof, it can be worn when doing exercises in the pool.

To give a specific example where 'perspex' is of great value I have had some splints made of it for opponents polio paralysis, and have a patient with bilateral paralysis who, without the splints, found considerable difficulty in washing, using a tooth brush, and dressing himself, but when wearing the splints he is able to carry out all these actions easily and comfortably, and added to this the splints are inconspicuous—a factor of great importance, at least to the patient.

Surely no one suggests that "perspex" is a complete substitute for plaster of Paris or that it is the ideal plastic for all selected orthopaedic conditions, but let us at least recognize its advantages and acknowledge that Scales and Herschell have overcome several obstacles in its use—obstacles which some of the commercial experts considered were almost insurmountable. Further investigations in the use of plastics in orthopaedics are needed and are continuing at Stanmore—I am, etc.

Royal National Orthopaedic
Hospital, Stanmore

JOHN A. CHOLMELEY

Third-generation Syphilis

SIR,—There appeared a case report by Dr C. J. V. Hellwell in the *Journal of Aug. 11* (p 186) purporting to be one of third-generation syphilis. The boy appears to be a congenital syphilitic but evidence is lacking to indicate that his mother is Dr Hellwell based his case on the negative blood test in her husband, the statement that she never had syphilis but that her parents died of it. It is not unusual for a woman to be ignorant of ever contracting syphilis. There was no supporting evidence that her parents really died of the disease.

It is recognized that congenital syphilis occurs less frequently from wife to husband than husband to wife. The age of the infection in the sexual partner is an important factor. Such data as her present age and first sexual exposure were not included in the report.

The occurrence of third generation syphilis is recognized. Its frequency is unknown since the facts are not always obtainable. Basic necessary information was not included in the report to justify the conclusion—I am, etc.

C. C. WEDDERBURN, M.B., Ch.B.,

Medical Department, Kings of Jamaica

Venerical Diseases Officer

Infant Feeding and Duodenal Ulcer

SIR,—There is undoubtedly an increase in the incidence of duodenal ulcer at the present time, and it seems to be occurring at a more early age. The custom of feeding infants at four hourly intervals by day, and of giving no feed at all during the night, began to be taught and rigidly followed after the 1914-18 war. The hungry child very often spends the last hour of the period wailing lustily, while the conscientious parent parades the floor with an eye on the clock until the appointed hour arrives. This must mean that for several hours by day and for a longer period during the night the child's stomach is in a state of anticipatory peristalsis actively secreting hydrochloric acid and with probably an accompanying pylorospasm. In a child of such a habit this may provide the predisposing factors for the development of ulcer in later life. The remedy would appear to be more frequent feeding of this type of infant by day and permitting a feed during the night—I am, etc.

J. M. MORGAN

Housing, Health, and Unwise Spending

SIR—I would like to supplement Dr Frewen Moore's comments (Oct 13 p 408) on Dr H. Nelson's valuable paper on housing and health. It is not sufficient to enumerate the common types of unwise spending by the poorer classes; we must try to understand the reasons for it. Take for instance the family living in a three roomed back to back, or four roomed dwelling of the type still occupied by probably the great majority of the city working classes. On what can they spend their surplus earnings? The cramped squalor of the home precludes the pursuit of any hobbies or cultural or constructive interests of any kind. The more well-to-do family has a garden, spare ground on which to build a workshop, enough rooms and big enough rooms in which to entertain friends or indulge in relaxation. The urban working-class family lives under or on top of another family or is jammed up on each side with a number of similar families and they all have children. In addition to the crowding and the squalor there are therefore incessant noise and lack of privacy. The home in fact, a place to get away from. In such circumstances what can the wage-earner spend money on but cigarettes, cinema, betting, drink? Even to keep a bicycle may be impossible for want of place to house it. In my opinion it is of immense importance that this aspect of the life of our poorer classes should receive prominent attention in the planning of our future—I am, etc.

—Z.M.

E. H. WILKINS

Training for Released Service Doctors

SIR—Lieut-Col F. F. Hellier in his letter (Oct 6 p 477) raises a most pertinent point and one of great import to those in the Services about to be released.

I should like to give my personal experience of applying for a Class III appointment as a registrar in dermatology at a salary of £100 per annum. The necessary form of application was forwarded to the British Postgraduate Medical School and a personal visit made immediately I was demobilized. My qualifications and reasons for applying were stated as follows:

I was keen to become a dermatologist, and at the beginning of the war was hon. assistant dermatologist at the Royal United Hospital, Bath, following the appointment of medical registrar to that hospital. I had not started as a consultant in private and was still in general practice in a town 7 miles away.

(2) I wish to study at the same time for a higher qualification in order to be in a position to apply for hospital staff appointments.

(3) The lease of my house, from which I practised had been terminated by me in 1943, at the first option (10 years) as I did not intend to return to general practice. I have been unable to sell the practice and there is now only a nucleus which, without a house, appears difficult to sell.

I was informed that I was ineligible under the Government Scheme Class III (Registrarship) as I had been established before the war in general practice and had not sold my practice and would also have been ineligible had I started as a consultant in private. The only class open to me was Class II (14 days' refresher course for general practitioners).

Surely the Government policy is to assist in training men who may later prove useful members of the staffs of hospitals treating large numbers of the community over a period of years, and not to exclude men on technicalities from financial assistance with postgraduate study. The only course open to me now is to do postgraduate study at my own expense, and therefore for a short period (three months) due to financial limitations.

The above facts will, I think, be of interest to those in the Forces who may be trying to work out their post-war plans and are expecting financial assistance from this source.—I am, etc.,

C. D. EVANS,
Late Colonel, A.M.S.

Nutritional Macrocytic Anaemia: Correction

We apologize for a misprint in the letter on nutritional macrocytic anaemia by Dr. L. E. Glynn, Prof. H. P. Hims-worth, and Dr. A. Neuberger, published last week (Oct. 20, p. 550), by which the word "devoid" was omitted in the seventh line. The sentence should run: "It may therefore be of interest to your readers to know that recently we have found that rats on a diet devoid of methionine develop a macrocytic anaemia characterized by changes in the peripheral blood and in the bone marrow similar to those in human nutritional macrocytic anaemia. . . . The development of this anaemia is not prevented by large supplements of cystine or of iron."

Obituary

W. B. CANNON, C.B., LL.D., M.D.

A wide circle of physiologists the world over will feel a personal loss by the passing, on Oct. 2, of Dr. Walter Bradford Cannon, who for many years held the George Higginson Chair of Physiology at Harvard University. Though a world figure in science, Cannon was essentially a Harvard man, for there he graduated in 1896, and there, with characteristic fidelity, he remained with few interludes until his retirement in 1942, first as instructor in zoology, then in physiology, next as assistant professor of physiology, and finally from 1906 to 1942 as professor.

He was one of the now rapidly dwindling number of all-round physiologists whose inspiration, exerted through generations of pupils, will long continue to be felt, and few scientific men can hope to have both so wide and so beneficial an influence on the evolution of their subject as was his. He brought to his subject not only wide experience and knowledge, but also a broad philosophy, an artistic imagination, and an admirable clarity of expression. His initiation in 1898 (at the age of 27) in the technique of the opaque meal in x-ray study of the movements of the alimentary canal was by itself enough to ensure him an important place in the history of the medical sciences. The classical work of Cannon and his collaborators, now generally known, and summarized in his *Bodily Changes in Pain, Hunger, Fear, and Rage*, was an outstanding example of the value of imagination in research, and his book *The Wisdom of the Body* was a further revelation of his wide philosophical outlook on biological phenomena. The accepted theory of the humoral transmission of the nerve impulse has much of its factual foundation in the series of investigations by the Harvard School, led by Cannon.

In the interlude occasioned by the first World War he served in the British Military Service in 1917, and engaged in work on traumatic shock, partly in collaboration with the late Sir William Bayliss. He later became a lieutenant-colonel in the U.S. Army Medical Corps, and served with it till 1919. He was decorated C.B. in 1919, and awarded the Distinguished Service Medal of the U.S.A.

Many other honours and distinctions very properly fell to his lot. Among these were Croonian Lecturer, Royal Society, 1918; foreign member, Royal Society, 1939; Linacre Lecturer, Cambridge, 1930; Baly Medal, Royal College of Physicians of London, 1931; President, American Association for the Advancement of Science, 1940; honorary degrees of Yale, Liège, Strasbourg, Paris, and Madrid; foreign member of several learned academies; Harvard exchange professor, 1929-30; and visiting professor to Peiping Union Medical College, 1939.

He died at the age of 73, after a good deal of ill-health. His calm, happy personality will be remembered with affection by those whose privilege it was to know him.

C. L. E.

T. P. PUDDICOMBE, D.S.O., M.B., D.P.H.

Dr. Thomas Phare Puddicombe, who died suddenly at Great Torrington on Sept. 29, was born in 1877, the youngest son of Robert Puddicombe of Kilverleigh Manor, Beaford, North Devon. He was educated at West Buckland School, King's College, London, and St. Thomas's Hospital. He served with distinction in France from November, 1914, to May, 1919, in command of the 25th Field Ambulance, with the rank of lieutenant-colonel, R.A.M.C. He was thrice mentioned in dispatches and was awarded the D.S.O. Before this he had entered the Local Government Service in 1906 and saw service at Croydon as deputy medical officer of health and at Plymouth as senior medical officer before going to Essex in 1920 to fill the new post of deputy county medical officer of health in 1930. Thus when he retired in 1942 he had seen 35 years' service with local authorities, 22 of which had been spent with the Essex County Council.

Dr. W. A. BULLOUGH writes:

When we in Essex heard of his death our minds went back to the day he left us in March, 1942, when so many good things were said about him by all ranks in the service, from the chairman of his committee to the humblest member of the clerical staff of the Public Health Department. His own quip (he was full of quips and pleasantries) on this occasion was that he felt like a man attending his own funeral, because that was when most nice things were said about people. We feel some pleasure that we were able to say these things to his face and have not left them all to be said after he is dead. His geniality, kindness, sympathy, and consideration will long be remembered by those who came into contact with him, particularly a very wide circle of parents in Essex, who have much reason to be grateful to him in his capacity as mental expert for his tact and kindness. If there was a problem to be solved that involved the human element, official or unofficial, "Tay Pay" (as he was affectionately known) was the man to solve it, and he is gratefully remembered as a guide, philosopher, and friend by many in Essex. Those who were privileged to visit him in his bungalow in Rothesay Avenue, Chelmsford, saw the foundation of his character—a great home lover, one who was proud of his home and his garden. He was keen on indoor and outdoor sport—he founded and was the moving spirit in a Badminton Club in Chelmsford. Whatever the game, he played with enthusiasm and vigour. Truly he was a leader of men in more ways than one.

Personally, I was most indebted to him for his great loyalty. No matter how much we disagreed, one could always depend upon "Tay Pay" to be loyal to the extreme. His industry amazed me; quietly and methodically he got through an immense amount of work. And, above all, I admired and liked him for his straightforwardness. If he disagreed he said so, and that was the end of it. One always knew that what he said he meant. I always found him willing to do anything, and he had that inestimable characteristic which made him an ideal deputy—a complete absence of self. I never had any fear about the School Medical Service in Essex under his control, and he never let me down. In his capacity as mental expert I never found a flaw in his diagnoses and estimations.

Outside Essex he had many interests. He was a Fellow of the Society of Medical Officers of Health, and for many years represented the School Medical Group on the executive committee of the society. He was a member of the Central Association for Mental Welfare, and was also keenly interested in the Essex Rural Community Council, and was, in fact, chairman of the health committee for many years. He also gave much attention to the scheme for the preservation of rural England. He was greatly missed by the council when he left Essex. He told us that he intended to live the life of a country gentleman in the West Country when he retired and we felt that there was no one more fitted to do so. Some of us were privileged to spend short wartime holidays with him among his own folk. It is fitting, indeed, that he should have died in his own beloved Devon. To his wife and son, Capt. Robert T. M. Puddicombe, R.A.M.C., who arrived home on leave from Italy just too late to see his father alive, we extend our deepest sympathy.

Dr. GERALD QUIN LENNANE, who held the post of M.O.H. for the metropolitan borough of Battersea from 1906 to 1934 died on Sept. 12 after a long illness. He was born at Galway in 1869, and after qualifying in Dublin in 1891 went to sea as a ship surgeon, and then took the F.R.C.S.I. and the D.P.H. in 1900. In 1914, at the age of 45, he volunteered for a commission in the R.A.M.C., served in France, was mentioned in dispatches, and awarded the Military Cross in 1917. After

returning to civil life he was for 16 years examiner in hygiene at the R A M College, and Battersea Borough Council named a block of flats after him in recognition of his long and valuable service. Dr James Fenton in the course of a tribute in the *Medical Officer* has written: "It was Lennane's custom to get a touch with young men on their first taking up an appointment as M O H of a metropolitan borough and offer his advice and experience in any problems which might present themselves to the newcomer. This approach was always made in a kindly way, and was often associated with Lennane's well known hospitality. The only reward he wanted was the knowledge that he might occasionally be of some help. In debates at meetings of the Metropolitan Branch of the M O H Society and at his club he displayed an old-world courtesy which endeared him to his wide circle of friends. In Battersea he was highly respected by his councillors for the courageous way he tackled many public health problems."

We regret to record the death on Sept 14 of Dr. GEORGE HALL of Stockton-on-Tees, at the age of 66. He was born at Macduff, Banffshire, and educated at Banff Academy Grammar School and at King's and Marschal College, Aberdeen. At Aberdeen University he graduated M A in 1900, proceeding M B, Ch B in 1905. He had been a member of the B M A for nearly forty years, contributing an article on "Spontaneous inversion of the Uterus" to the *Journal* in 1908. Having travelled round the world after completing his studies he took up practice in Stockton. For 38 years he was in close touch with the Stockton and Thornaby Hospital, being appointed senior surgeon in 1918 and continuing on the honorary staff until 1944, after having served five extra years at the request of the hospital committee. He was chairman of the Stockton Division of the B M A from 1929 to 1931 and an important member of the committee of the North of England Cancer Research Campaign for many years. A colleague writes: "Not merely as physician and surgeon will George Hall be missed in the whole district but as a beloved friend. He was a humble, reticent, and tireless worker in the community, being held in high esteem and affection by colleagues and townspeople alike, countless of whom owe their well-being and very lives to his skill and unbounded devotion to duty. A gloom has been cast over thousands by his passing and he will be sorely missed by his patients and friends."

Mr. RALPH MARSH DE MOWERAY, FRCS, of Lymington, Hants, who died on Sept 24, had been for many years surgeon to the Lymington Cottage Hospital and the Milford-on-Sea War Memorial Cottage Hospital and consulting surgeon to the Fenwick Cottage Hospital at Lyndhurst. Born at Vinosington on Oct. 16, 1887, son of the Rev J H M de Mowbray, he entered St Thomas's Hospital in 1905 from Marlborough College and qualified in 1914 taking soon afterwards the FRCS. During the war of 1914-18 he served first for a year at the British Red Cross Hospital at Netley, and then for over three years, with the rank of captain, R A M C as surgical specialist and officer in charge of the surgical division of No. 34 General Hospital at Deolali India. Mr de Mowbray had also been house-surgeon, casualty officer, and resident anaesthetist at St Thomas's Hospital, and house-surgeon at the Royal Hants County Hospital, Winchester. He joined the British Medical Association in 1919.

Dr. DAVID JOHNSTON JONES who died at Llandudno on Sept. 24, aged 91, was educated in Edinburgh, London and Paris, graduating M B, C M E d in 1876, and M D in 1879. After serving as house-surgeon at the Liverpool Royal Infirmary he became senior assistant medical officer to the Kent County Mental Hospital, near Maidstone, and was then for a long time medical superintendent of the L C C Mental Hospital Banstead. Dr. Jones joined the British Medical Association in 1880. At the date of his death there were only three living members with as long a membership of the Association though 66 years is not a record, the late Sir James Crichton-Browne having remained in membership for 69 years.

Dr. WILLIAM McDUGALL who died on Sept. 29, had practised for 48 years at Wallington in Surrey. The son of a Highland minister, he went to school at Aberdeen and then to the University of Edinburgh where he graduated M B, C M in 1889. After a sea voyage and a house appointment in Carlisle, he settled in the remote township of Teneue, on the north coast of Scotland. His work there demanded journeys on horseback as far as forty miles from home over wild country, a single visit to a patient with pneumonia would sometimes take him two days and a night. After his first marriage he came south to a very different kind of practice in a village two or three miles from Croxson where something of a Scottish

community was forming round the Presbyterian church. In half a century Wallington grew out of recognition, and Dr McDougall, having started work alone, eventually became the senior partner of a firm of four. In 1913 he had joined forces with Dr A T Moon, FRCS, and in 1916-17 he was able to spend a year in the R A M C at the Connaught Hospital Aldershot. From the foundation of the Carshalton War Memorial Hospital, about 1923, he was a member of the active staff until he became consulting physician ten years ago. He was "writes a colleague, a first-class physician, painstaking to a degree. Restrained and even dour with strangers at first he had a friendliness and understanding which stirred the affection of his patients into a devotion deep and abiding. He was a man of unalterable integrity whose whole life was a service to his fellows, carried to the full and to the end. His rare and deep humour, his generosity to all in need, and the religion he lived so thoroughly, made him an example which his friends must always remember, and which must always influence them." Dr McDougall died at 79 years of age, having doggedly continued his work throughout the war. He leaves a widow and two sons and two daughters.

Dr. JAMES CECIL MOTTRAM, director of the research laboratories of Mount Vernon Hospital, Northwood, died on Oct. 4 at Northwood. He was born at Holt, Norfolk, on Dec. 12, 1880, only son of James Mottram, and was educated at the Beacon School, Sevenoaks, University College and Hospital, London, and St John's College, Cambridge. He graduated M B, Lond in 1903, and took the D P H Camb in 1906. After being as first assistant at the Ascot County Asylum and bacteriologist for the County of Worcester he became first assistant in the cancer research laboratories of the Middlesex Hospital. During the war of 1914-18 he served as lieutenant, R N V R, attached to the Royal Naval Experimental Station, Stratford, and advisory expert at the Camouflage School G H Q. After returning to civil life Mottram was appointed director of the research department of the London Radium Institute and continued in that post when the Institute joined up with the Mount Vernon Hospital at Northwood. He made numerous reports to the Royal Society, to the Royal Society of Medicine, the Linnæan Society, the Zoological Society of London and the Pathological Society on cancer radiology and animal coloration. The last named subject was, with fly-fishing and the study of trout and trout fisheries, Mottram's principal hobby. He wrote articles on animal coloration and on camouflage for the *Encyclopaedia Britannica*.

Dr. ERNEST LE CRONIER LANCASTER formerly a leading member of the profession in Swansea and well known as a specialist died at Lyme Regis Dorset, on Oct. 4, in his 81st year. After taking his B A, with first-class honours in 1881 at the University of Oxford in 1883 he went to St. George's Hospital for his clinical course graduating M B, B S in 1887. At St. George's he served as house-physician, resident obstetric assistant, and demonstrator in anatomy and pathology. He became physician to the Swansea Hospital, to the Aberavon and Port Talbot General Hospital and to the Swansea and South Wales Institute for the Blind and he held the rank of lieutenant-colonel, R A M C (T). Dr. Lancaster joined the B M A in 1892 was elected chairman of the Swansea Division in 1910 and president of the South Wales and Monmouthshire Branch in 1914. He was a past-president of the Swansea Medical Society, a J P for the County of Glamorgan, and for many years acted as honorary curator of the local museum. In retirement he undertook the same duty for Lyme Regis. Two branches of zoology attracted him most—the study of molluscs and shell-fish and the study of molluscs—and he was for many years an active member of the Conchological Society of Great Britain and Ireland and of the Malacological Society of London. His professional writings were several papers in the *Transactions of the Clinical Society* during the 'nineties, and a paper on heredity and disease published in these columns in 1910.

Dr. JAMES McDONALD TROUP, consulting physician to the Presbytera Hospital and the doyen of the medical profession in that city, died on July 31 in his 78th year. A native of Huntly, in Scotland, he was the youngest son of the Rev. Robert Troup, and after early education at Madras College went to St. Andrews University where he graduated M A with honours in 1887. He won the Guthrie Scholarship from St. Andrews to Cambridge, was 7th Wrangler in the Mathematical Tripos of 1890 and went on to King's College Hospital London with a senior scholarship. He took his M B, B Ch Camb in 1896, and was house-surgeon at King's to Watson Cheyne. In the following year he went to South Africa to an appointment at Grahams-town, and later for a time practised at Somerset East. He

settled in Pretoria in 1902, and during 43 years there his life was devoted to his patients; he soon gained a reputation for sound judgment and for skill in diagnosis and treatment; moreover, he was one of those practitioners whose advice and counsel were sought on many personal matters outside the strict range of his profession. The *South African Medical Journal* has published a number of tributes to Dr. Troup from colleagues, and a long appreciation of his character and gifts and his attitude towards the science and art of medicine by Dr. A. Piijper, written from 25 years' personal knowledge. One passage may be quoted here: "Troup had a persuasive manner and his authority was readily accepted. He was a marvellous diagnostician and had a horror of mechanized medicine, as it is called. Yet he used the laboratory to the utmost, but it was merely to confirm his ideas or to give him the needed quantitative data. If he had to subject a patient to more than one test he blamed himself. Difficult cases were first discussed with the pathologist, on equal terms. Working with Troup was a delight to the laboratory-man. Even in the early days large numbers of his patients had laboratory work performed, and this being unusual in those days, I once asked him how the patients took it and whether it did not detract from his status. He countered by saying that the opposite was the case: his patients realized the purpose and that their doctor was on the right track." Dr. Troup had been a member of the British Medical Association since 1897.

Universities and Colleges

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Lister Memorial Lecture

Sir Howard Florey, F.R.S., delivered the Lister Memorial Lecture at the Royal College of Surgeons on Oct. 11, taking as his subject "The Use of Micro-organisms for Therapeutic Purposes"; it will appear in a future number of the *British Medical Journal*. At the end of the lecture he was presented with the Lister Medal for 1945 which had been awarded to him for his distinguished contributions to surgical science.

A quarterly meeting of the Council of the College was held on Oct. 11, with Sir Alfred Webb-Johnson, Bt., President, in the chair.

A Diploma of Fellowship was granted to David Barrett Feather (Leeds Medical School).

Diplomas of Membership were granted to the following successful candidates: W. H. Lonsdale, E. C. Hutchinson, P. M. Jeavons, C. H. de Boer, Lucy M. Dunkerley, R. L. Greenwood, H. Wainstead, H. A. Lane.

Diplomas in Physical Medicine were granted jointly with the Royal College of Physicians of London to F. J. Bach and E. J. Crisp.

Diplomas in Child Health were granted jointly with the Royal College of Physicians of London to the following successful candidates: H. I. C. Balfour, H. Blair, Agnes A. Brash, E. H. Brown,

F. B. Cadman, A. Comfort, Nancy D. Cox, J. G. Dathan, L. J. S. Derham, Glenys M. M. Donaldson, F. R. M. Elgood, Elizabeth de C. Falle, I. W. Gallant, Susanna Gordon, Mona Griffin, J. R. Griffiths, Ursula Jerram, A. Kahan, Margaret Kemsley, Vivien U. Lutwyche, Helen M. C. Morley, Joan L. Noak, G. E. Paget, Margaret Pardee, H. E. Parry, P. E. Polani, Phyllis Poyner-Wall, L. S. Prasad, R. J. P. Pugh, Mary M. E. Rutter, Vivian M. N. Osborne, D. E. Yarrow, S. S. Yudkin, C. Zahra Neumann, H. L. Zondek.

A Leverhulme Research Scholarship was granted to Mr. P. B. Ascroft, F.R.C.S., for research on the pathology of head injuries.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

Dr. J. A. Nixon, Emeritus Professor of Medicine in the University of Bristol, will deliver the Dr. Alexander Black Lecture on "The Health and Safety of the Merchant Seaman" at the College (9, Queen Street, Edinburgh) on Friday, Nov. 2, at 4 p.m. The lecture is open to all graduates and senior students.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At the annual meeting of the College, held on Oct. 17, the following officers were elected for the ensuing year: *President*, Mr. J. M. Graham. *Vice-President*, Prof. R. W. Johnstone. *Secretary and Treasurer*, Mr. K. Paterson Brown. *President's Council*, Sir John Fraser, Bt., Dr. G. Ewart Martin, Mr. Francis E. Jardine, Mr. W. Quarry Wood, Mr. Walter Mercer, Prof. J. R. Learmonth. *Representative on the General Medical Council*, Mr. Henry Wade. *Convener of Museum Committee*, Mr. W. Quarry Wood. *Librarian*, Dr. Douglas Guthrie.

At a meeting of the College held on Oct. 17, with the President, Mr. J. M. Graham, in the chair, the following, having passed the

requisite examinations, were admitted Fellows: J. Boyes, A. I. Bremner, J. A. Chalmers, A. W. Chambers, Prudence Halton, J. P. Harpman, G. Hay, W. A. N. Inglis, E. M. Innes, Alberta M. Jean, Kathleen M. Long, R. N. Martin, D. Telford, N. Whalley.

The Services

Lieut.-Col. (Temp.) H. Rees and Major (Temp.) S. K. Dart, I.M.S., have been mentioned in dispatches in recognition of gallant and distinguished services in the field.

The following appointments and awards have been announced in recognition of gallant and distinguished services in North-West Europe:

C.B.E. (Military Division).—Brig. (Local) E. Bulmer, O.B.E. Brig. (Acting) J. T. McConkey, and Col. (Temp.) F. A. Bear, D.S.O., M.C., R.A.M.C.

O.B.E. (Military Division).—Cols. F. G. Flood, M.C., and R. Shaw, M.C., late R.A.M.C.; Cols. (Acting) J. P. Douglas, M.B. and F. McL. Richardson, D.S.O.; Cols. (Temp.) J. P. J. Jenkins, T.D., H. E. Knott, and G. G. Talbot, T.D.; Lieut.-Cols. (Temp.) J. C. Anderson, W. S. C. Copeman, R. Evans, F. N. Foster, T.D., E. Hutcheon, A. B. Kerr, T.D., and W. R. Logan, T.D., R.A.M.C. Cols. C. F. Abbott and C. G. Wood, Lieut.-Cols. D. Campbell, K. J. Coates, C. D. S. Leef, and J. Tanzman, R.C.A.M.C.

M.B.E. (Military Division).—Major R. B. Hunter, Majors (Temp.) D. J. Johnson, W. Michie, R. O. Murray, and R. O. G. Norman, and Capt. K. C. Burrow, R.A.M.C.; Majors W. A. McKibbin and E. Wolstein, R.C.A.M.C.

D.S.O.—Lieut.-Col. (Temp.) M. W. Gonin, R.A.M.C.

M.C.—Major (Temp.) J. L. Chisnall, Capt. R. D. S. Jarvis, G. D. H. McQuitty, I. Morris, and J. Sheehan, and Lieut. R. Major, R.A.M.C.; Capt. K. A. Campbell, R.C.A.M.C.

The following appointments and mentions have been announced in recognition of distinguished services during the liberation of prisoners from German concentration camps.

O.B.E. (Military Division).—Lieut.-Col. (Acting) F. S. Field, Lieut.-Col. (Temp.) J. A. D. Johnston, M.C., and Lieut.-Col. F. Lipscomb, R.A.M.C.

M.B.E. (Military Division).—Capt. P. O'Donnell and D. Perkin, R.A.M.C.

Mentioned in Dispatches.—Major H. A. Tuck; Majors (Temp.) E. M. Griffin, G. M. C. Smith, and D. J. Waterston, M.B. Capt. G. M. Baker, I. Gluck, J. Kraus, D. T. Prescott, and W. Winterbottom; Lieuts. S. Durrant and N. Winter, R.A.M.C.

Repatriated.—Major J. W. D. Bull, R.A.M.C.

Dalkeith Presbytery, in Midlothian, has sanctioned the erection of Newbattle Parish Church of a three-light stained glass window to commemorate the members of the R.A.M.C. who were stationed at Newbattle Abbey in the early years of the war.

Medical Notes in Parliament

On Oct. 18 the Parliamentary Medical Group met at the House of Commons and elected Dr. Haden Guest as chairman, Mr. Hugh Linstead as hon. secretary, and Sir Henry Morris-Jones as hon. treasurer. The Group decided to meet monthly. The next meeting will discuss demobilization. Dr. Haden Guest was re-elected the representative of the Group on the Central Medical War Committee.

The Parliamentary Medical Committee of the Labour Party under the chairmanship of Mr. Somerville Hastings, will work in close co-operation with the Health Group of the party.

Distribution of Medical Man-power.

Mr. LAWSON stated on Oct. 16 that the present ratio of R.A.M.C. medical officers in the Forces to personnel under their medical charge is 2.57 per 1,000. All effective medical officers whether engaged on administration, hygiene, hospital work, attendance on unit sick, are included in the ratio. The proportion of doctors of all kinds in this country to the civil population is 0.74 per 1,000. He added that circumstances in the Army and civil life are so different that a true comparison is impossible.

Sir GIFFORD FOX on Oct. 17 asserted that the present strength of medical officers in the R.A.F. was 2.27 medical officers per 1,000 men, which compared with one doctor per 3,500 of the civil population. He asked why it was necessary for the proportion of doctors in the R.A.F. to be eight times

NOT the least of the many properties of a nylon monofilament suture is its great strength, as revealed by this photograph in which it is shown under considerable tension. For instance, a suture of 012" diameter will withstand a pull of some 7 lbs. You can be certain, too, that each succeeding suture will be an exact counterpart of the first. Nylon monofilament sutures are strong, smooth, supple and water-resistant, and will remain uninjured by water or steam at the highest temperatures normally used for sterilising. A pattern card can be obtained from your usual Medical Supply House.

IMPERIAL CHEMICAL INDUSTRIES LTD

coupled with the injection of toxins of assured potency by experienced observers having the necessary time, the Schick test can be a valuable indicator of the existence of blood antitoxin where there was formerly none. What it cannot do is to vouch for the permanence of blood antitoxin or tell us the ability of the individual to withstand infection. The test therefore finds its true place in surveys of the inoculated as a check of the potency of the antigen. After such a survey, Fulton and his colleagues (*British Medical Journal*, 1942, 1, 352) have assured us of Schick conversion rates of 97 to 100% with doses of 0.1 ml. and 0.3 ml. of A.P.T. of reputable manufacture and so suggest a posterior Schick test only for small samples of the inoculated.

In this area difficulties of staffing and pressure of other work limit us to the inoculation of children, and I know that in many other areas the position is similar. I, for one, would be content if I could get all the children, including those now partly inoculated, to complete the full course of injections.—I am, etc.,

JAMES GRANT,
Medical Officer of Health.

Gateshead.

Staple Introducer for Recurrent Shoulder Dislocation

SIR,—Sir Heneage Ogilvie's description of the Johannesburg staple driver for the repair of recurrent dislocation of the shoulder prompts me to describe the staple introducer and operative exposure I have used over the past four years. The instrument was made for me in the R.A.F. workshops, Karachi, when I was orthopaedic specialist at No. 1 and No. 6 Base Hospitals there. We often had reason to be grateful for the skill and willing co-operation of the R.A.F. technicians in the early days of 1942. They also made for me a set of Smith Petersen nails of a standard equal to any commercial product.

The instrument is illustrated in the sketch. The staple is held in the hinged clamp, which is tightened and released by means of the longitudinal screw. The staples are conveniently made

from an ordinary stainless-steel table knife, which provides steel of the proper temper. For the exposure of the labrum and the neck of the scapula I have found it unnecessary to divide the coracoid. The exposure is through the delto-pectoral sulcus. The short head of biceps and coraco-brachialis are retracted medially to expose the subscapularis and the capsule, which are divided in the direction of the fibres of the former and not transversely. This gives adequate exposure even in the most muscular individual if attention is paid to perfect haemostasis. One transverse suture of catgut through subscapularis and capsule repairs these structures after the staple has been driven home.—I am, etc.,

Hairmyres Hospital, East Kilbride

J. S. MAXWELL.

Prevention of Burns in Children

SIR,—A recent case in the coroner's court refreshed my memory concerning the law with regard to the protection of open fireplaces in private houses where there are children under 7 years of age. I do not know whether this law applies to

open electric fires. With few exceptions manufacturers of these fires do not seem to give much thought to this matter. It would appear to me that the most suitable protective guard for such a fire should be included in the structure. A protective mesh is useless unless it is at such a distance from the element that a child's fingers can be prevented from touching it. I would suggest that the element be protected by a guard which is convex forward and the element placed at a safe distance from it.

I have in the last few months encountered five cases in children where either one or both hands have been crippled as a result of handling the hot element of an electric fire. The ages of the children have ranged from 1½ years to 8 years of age. Perhaps from a legislative point of view the Board of Trade could insist on such a guard being included in the specifications of all open electric fires and gas stoves.—I am, etc.,

Gloucester City General Hospital,

EMLYN LEWIS.

Deafness from Rubella in Pregnancy

SIR,—In the *Journal* of June 16, 1945 (p. 845), you published figures which I had collected on the subject of rubella during pregnancy causing deafness in the child. In view of the interest which is being taken in this matter, I give you my figures as they now stand.

Deaf children born in 1940-1: Boys 64, girls 38; total 102.

History of rubella during first 4 months of pregnancy: Boys 16 girls 20; total 36.

Some of these children have defects of the eyes and some have defects of eyes and heart. I have the birth weight of 19, fifteen between 5 and 6½ lb. (2.2 and 2.9 kg.); two 7½ lb. (3.4 kg.); one 4½ lb. (2.0 kg.); one 3½ lb. (1.5 kg.). In a few cases the intelligence has been questioned, but most of those with whom I am dealing at the moment show average and even above average intelligence. There are a further 11 cases in which, from the symptoms given, I suspect rubella, but it was not diagnosed.

Of the total of 102 children, 40 are left-handed or ambidextrous, 16 of these having left-handedness in the family; and 15 are right-handed but have left-handedness in the family.

Deafness is accounted for in 15 cases by meningitis and in 8 by heredity. In the remaining 43 cases in which deafness was not due to rubella in pregnancy there was the following disease history during the first three years of life: measles, 15; whooping-cough, 10; pneumonia, 9; bronchitis, 8; in one case the mother had mumps during pregnancy. In 5 cases instruments were used at birth.—I am, etc.,

London, S.E. 4.

SYLVIAN M. MARTIN.

"Cord Round the Neck"

SIR,—With regard to the controversy whether this condition can cause stillbirth, a case which I had a few years ago may be of interest.

The woman was about 28 years of age, and the whole antenatal period was quite normal. At the confinement the foetal heart was heard beating normally, and the presentation was a vertex. The descent proceeded uneventfully until the head was well down on the perineum, and then no further progress took place, although the uterine contractions were strong and regular at about three-minute intervals. As soon as the head touched the perineum the usual routine examination had been made for cord round the neck, when it was found that there were at least two loops of the cord in this position, but under such extreme tension that it was quite impossible to pull a loop over the head to relieve it.

As it seemed from previous examinations of the patient that the only cause of obstruction must be the cord, and as no further descent was taking place, there seemed no other course but to sever the cord and deliver as quickly as possible. This was done, and the baby delivered (without instruments) very soon afterwards. The cord was found to be abnormally long, being wound twice round the body and four times round the neck, making a total length of approximately 6 ft. (1.83 m.) from placenta to foetus. The child was not breathing, and I could not detect any pulsations in the foetal end of the cord. The usual methods of revival were tried, but unfortunately with no effect.

I decided at the time (and I have not yet had reason to alter my opinion) that death occurred shortly before delivery due to the abnormal position of the cord, which caused either

obstruction of the foetal circulation to the placenta or, by pressure on the neck, interference with the circulation to the brain, or possibly both conditions—I am, etc.,

Slough

H TUDOR EDMUNDS

Nomenclature of Ekblom's Syndrome, or the Fidgets

SIR.—The condition described by Ekblom (*Acta med scand* 1944, 118 197, 1945, *Suppl* 158, and your annotation of Jan 19, p 95) has been recognized by the laity since the 16th century at least. The *New English Dictionary* has

"Fidge, v. *Obs* (1) To move about restlessly or uneasily. 1577 Breton Some [dame] would fidge, as though she had the itch

Fidget, sb (1) A condition of vague physical uneasiness seeking relief in irregular bodily movements. App first used in the *fidgets* (s) (now always pl) as if the name of a malady or pathological symptom (sometimes in definite pathological sense see quotation 1876) 1876 Bartholow *Mar Med* Wakefulness from unrest of the peripheral nerves (fidgets) and similar causes, will generally be relieved by the bromides"

This previous notice does not detract from Ekblom's merit, as he is the first to describe the condition in medical literature and to recognize its clinical importance. I suggest that minor degrees occur normally in many if not in all people. It is not uncommon to see a person sitting at rest, perhaps reading who frequently changes the position of his legs, crossing and uncrossing them without being conscious of the movements. Here the afferent stimuli never become sensations but cause the movements from a lower nervous level. At a further stage the stimuli enter consciousness and are not troublesome, and finally they may reach a clinical intensity of disturbance.

You follow Allison in using the word jitters. This word is not given in the *New English Dictionary*, but in *Wyld's Universal English Dictionary* 1936, Appendix 'Jitters, n pl American slang the creeps, nervous fluster, trepidation. There are two objections to this word. (1) Some degree of panic fear is connoted by it, and this is a matter of diagnostic importance since panic fear distinguishes Freudian psychoneurosis from the fidgets. Fear of fidgets is merely a justifiable dread of a disturbed night. (2) Although I have the greatest admiration for the vividness of American usage I feel bound by the advice of H W and F G Fowler that American usage should not be employed by English writers—I am, etc.,

Sheringham Norfolk

F H STEWART

Diuresis by Suggestion

SIR.—I have frequently observed this phenomenon but have never seen it described, so it may be worth recording. When the ureters have been catheterized I ask my house-surgeon, or someone else present in the theatre, to count the number of drops from the catheter over a period of say, 30 or 60 seconds. The patient is then asked if he would like a glass of beer or perhaps a cup of tea. In the majority of cases there is a material increase in the rate of flow within 10 seconds whereas the selected drink does not materialize for at least 10 minutes. Does the renal epithelium flush with pleasure at the prospect of an appropriate stimulant?—I am, etc.,

New Milton Hants

A BASIL ROOKE

"Deck Ankles" and "Travellers' Oedema"

SIR.—The following experience may be of interest as illustrating a phenomenon possibly related to "deck ankles."

In July, 1945, I was a prisoner on a train when the Japanese transferred a mixed party of prisoners of war and civilian political prisoners from Haiphong Road Camp Shanghai, to Fengtai Camp near Peiping. We left Shanghai in the evening of July 8, and next morning about a dozen men showed me oedematous feet and ankles. By the morning of July 12 out of 314 prisoners 24 of us were suffering from this condition, ranging from slight oedema to gross oedema with inflammation. On the evening of July 12, after a short forced march, we were able to lie down on a brick floor and next morning the majority of us were somewhat better. The last cases cleared up five days later. After our release in Peiping we were taken by train on Oct 5 to Tangu, near Tientsin in comfortable first-class coaches, the journey taking only about six hours, but in the

course of this short journey oedema recurred in several of the former patients. Col W S Flowers, of the British Red Cross Shanghai, subsequently informed me that there had been further recurrences in ex-prisoners travelling home by air from China. On Feb 2 I left Shanghai in the repatriation ship *Highland Chieftain* among some 1,200 passengers, the majority of whom were ex-internees or political prisoners, the SMO Cap Seville, R A MC, drew my attention to the incidence of deck ankles.

It was of course, impossible to carry out any biochemical tests under the conditions of a Japanese prison camp but I think the following factors are worthy of consideration.

(1) We left Shanghai with an atmospheric temperature of 90° to 100° degrees in the shade and a humidity of about 100%. A large number of the men had been working hard for two or three days loading the train, and the water supply during the four days on the train was inadequate. No salt was supplied on the journey.

(2) There was a chronic insufficiency of vitamin B in the camp diet. There had been 6 cases of frank beriberi and many more manifestations of vitamin B deficiency before the camp was moved.

(3) Men were sitting in cramped positions for four days and were only allowed to leave their seats to go to the lavatories and for short walks on two of the stations. On the other hand I had one of the worst pairs of inflamed feet myself although I was allowed to walk up and down the train to attend my fellow prisoners.

(4) Our diet had been deficient in proteins especially animal proteins—I am, etc.

London SW 16

STEPHEN D STUPTON

Islam and Medicine

SIR.—In your note on the influence of Islam on medicine (*Nova et Vetera*, March 16 p 401) the statement that "for the next 500 years the Muslims alone played a vital part in the evolution of humanity. They resuscitated Greek medicine by translating Galen's *Anatomy*" requires some modification especially as it is immediately followed by a reference to Hunayn ibn Ishaq. Hunayn, more generally known as John Nisius was a Christian and as Prof E Browne shows in his Fitzpatrick lectures the earliest translators and transmitters of Greek medicine were Christians expelled from Byzantium or Nestorian schismatics. The great medical school of Jundi Shapur was largely the result of this expulsion.

Splendid as were the contributions by Arabs and Persians, both Christians and Jews played a most important role. In fact Campbell writes "Although we have called this space of time the 'Arabic Period' it can with justice be called the 'Jewish Period,' as the Jews were closely identified with the medical culture of Islam in general." Hunayn translated much of the Hippocratic writings and Galen primarily into Syriac and thence into Arabic, and it was through Hebrew translations that Arabic literature was brought into Europe though the great period of Jewish translators was somewhat later between the eleventh and thirteenth centuries. The whole question is fully surveyed by Friedenwald in his recent volumes *The Jews and Medicine* (Johns Hopkins Press 1943)—I am, etc.,

G A AUDEN

Physical Therapy in Mental Disorder

SIR.—Dr Harvey Baird (March 23, p 447) has raised an interesting point in his pertinent question regarding the accuracy of the diagnosis of schizophrenia. I have however always been under the impression that it was Watson (of Rainhill) and not Shaw Bolton who originated the theory of the efficiency of the supragranular layer in dementia praecox. Shaw Bolton may have been and in fact, probably was, the first to publish these histopathological findings, but I believe it was Watson's theory which he took with him from Rainhill to Wakefield. He had free access to Watson's records and histological specimens. I am of course, open to correction but I like honour to be given where it is due. This I do know—that Watson firmly believed that dementia praecox was the result of an innate anatomical deficiency and he had a great deal of substantial evidence to prove his claim—I am, etc.,

Leigh

WRIGHT LAMBERT

Obituary

Dr. RHODES HAYGARTH died suddenly on Feb. 27. Born at Keighley, Yorks, in 1870, his early education was at Keighley Trade and Grammar School and he graduated M.B., C.M. at Edinburgh with first-class honours in 1895. He settled at Cross Gates, Leeds, in 1898 and practised there until his retirement in 1934. For several years he was medical officer of health for the district of Garforth. He served as lecturer and examiner to the St. John Ambulance Association for many years. During the first world war he had charge of a V.A.D. hospital and superintended a number of wards at the Killingbeck Hospital, in addition to organizing the medical services for a local Government factory. Dr. Haygarth died at Grange-over-Sands, Lancs, where he had lived since his retirement. He was a man of great kindness of heart, and was much beloved by his many patients and by all who knew him. He leaves a widow and one son.

With the death of Dr. GILBERT E. MOULD on March 16 there passed away one who, for many years, had been a familiar figure in the medical and sporting circles of Sheffield and the districts around. A son of the late Dr. Mould, superintendent of Cheadle Royal and the leading authority on mental diseases in Manchester and the North-West of England, he devoted his life to this specialty. From Cambridge he completed his medical studies at St. Mary's Hospital in 1894. After holding resident posts there, he worked as assistant medical officer at various mental institutions, until he became head of The Grange, near Rotherham, where he remained to the end of his life. For several years he was physician for mental diseases to the Sheffield Royal Hospital, and later to the Rotherham Municipal Hospital. For his ripe experience and sound knowledge of mental diseases he was highly valued by the profession of the district. A keen sportsman, he was well known in the hunting-field, and his holidays were always spent fishing in Scotland. A kindly, sociable man, he had a wide circle of friends, by whom his loss will be deeply felt. Dr. Gilbert Mould joined the B.M.A. in 1897 and had been chairman of the Rotherham Division, which he represented at two Annual Meetings.

Dr. BENJAMIN RIGBY JOHNSTON, who died on March 17, was educated at Rossall School and in Dublin and Brussels, obtaining the L.R.C.P.I. and L.M. in 1884, also the M.R.C.S.Eng. and the M.D.Brussels in 1890. After various resident appointments in Dublin hospitals he became ship surgeon in 1886 to the Far East; he then acted as assistant at Birkenhead for a year or two, and in 1888 settled at Grasmere, where he practised continuously for about 58 years, dying in harness at the age of 84. He was buried in Grasmere Cemetery after a service at St. Oswald's Church. In spite of one of the wettest days of the year the church was packed for a very beautiful service conducted by the present rector, and a previous rector, the Rev. B. Phillips, travelled up from Northampton to give an impressive funeral oration. Dr. Benjamin Johnston had mercurious interests, especially literary and archaeological, being secretary to Dove Cottage and the Wordsworth Museum; also he helped, and identified himself with, every good activity in the village. His brother, Dr. G. Ainslie Johnston, and all the members of the family have been greatly comforted by the receipt of a very large number of letters, the great majority of which contain the words: "Dr. Ben was the most useful man in Grasmere for 58 years." So ends a life well spent.

We regret to announce the death on March 18 of ARTHUR MORRELL JOHNSON of Bury, Lancs, chairman of the Bury Division of the B.M.A. in 1924-5 and its representative at seven Annual Meetings of the Association. He was born in 1887 in Nova Scotia and was educated at Dalhousie University, graduating M.D., C.M. in 1911. After the 1914-18 war, in which he served in Gallipoli, Egypt and France, and won the Military Cross, he went into partnership with his uncle, the late Dr. J. W. Johnson, at Bury. He was appointed honorary assistant surgeon to the Bury Infirmary in 1920, was promoted full surgeon two years later, and became consulting surgeon in 1935 and was for many years chairman of the medical board. He maintained his interest in military administration and held the rank of colonel, A.M.S.T.A., receiving the Territorial Decoration in 1930 and the C.B.E. in 1939. Col. Johnson again went on active service in 1940 and was in the retreat from Dunkirk. After spending many hours on the beaches he was taken on board a ship and collapsed from exhaustion; on his recovery he went to Egypt to take charge of the 6th General Hospital, returning home to resume his civilian practice in 1942. He was one of the oldest serving members of the Bury Insurance Com-

mittee, of which he had been chairman. He joined the B.M.A. in 1917 and served at headquarters on the Protection of Practices Committee and the Naval and Military Committee.

Mr. EDWARD HARRISON, consulting surgeon to the Royal Infirmary, Hull, and at one time the leading surgeon in that city, died at Paignton, Devon, on March 18, aged 88. Educated at Cambridge and St. George's Hospital, he gained first-class honours in physiology in the Natural Sciences Tripos of 1878, and graduated M.B. in 1883 and M.D. in 1898. He had been a foundation scholar and prizeman of Clare College and was for several years examiner in anatomy for Caius and Clare Colleges. After taking the F.R.C.S. in 1886 he was elected to the honorary staff of the Hull Royal Infirmary, and was president of the East Yorkshire and North Lincs Branch of the B.M.A. in 1898. He was an honorary life member of the St. John Ambulance Association and consulting surgeon to the military hospital at Hornsea. A man of wide cultural interests, Mr. Harrison had been president of the Hull Astronomical Society and of the Literary and Philosophical Society; he also took a great interest in the Hull Philharmonic Society and was deputy organist at Holy Trinity Church.

Dr. FRANCIS JAMES COUTTS, of Leytonstone, who died on March 18, aged 79, at the Connaught Hospital, Walthamstow, where he had been honorary surgeon for 32 years, qualified in 1895 from University College Hospital. He took the M.D.Lond. degree in 1897, and the F.R.C.S.Ed. diploma in 1913. At U.C.H. he served as house-surgeon and house-physician. For half a century he was an honoured figure in the local medical profession, and there can be few families in the borough of Leyton who have not directly or indirectly benefited from his skill and kindness. He remained very active for his years, and when in 1940 he was bombed out of his house he moved across the road and continued work right up to the day he was taken ill. He retired from his hospital duties last Christmas and at that time was chairman of the medical committee. Recently he received a silver salver inscribed with all the names of the hospital's medical staff. His sudden death soon afterwards came, as a shock to the Leyton and Leytonstone public, and he will be greatly missed. His widow, Dr. Jane S. Coutts, retired from practice a considerable time ago; she was an anaesthetist at the Walthamstow Hospital during the war of 1914-18.

The late Dr. VALENTINE CHARLES ROBINSON was educated at Cambridge and St. Bartholomew's Hospital. He gained first-class honours in the Natural Sciences Tripos of 1923, qualified in 1929, and took the M.B., B.Ch. in 1937 and the M.R.C.P. in 1940. Before joining the staff of the Central Middlesex County Hospital he had been clinical assistant at the St. John Clinic, Pimlico, and chief assistant in the electrical department at Bart's. During the war he was a physician in the E.M.S. A colleague writes: The death of this unique and lovable person has been a grievous blow to everyone at the hospital. Doctors, nurses, ward maids, and his patients all found his combination of charm, sympathy, and humour something quite out of the ordinary. Though burdened by a succession of illnesses he managed to succeed in an astonishing number of interests. He was a fine clinician, infinitely patient and thorough in both history and examination, and his accurate and neat notes are well known. He was deeply interested in all his patients apart from their illnesses, realizing better than most of us the importance of their homes and habits; his kindness and patience made them hold a deep affection for him. His general knowledge was prodigious and there seemed no subject on which he was not well informed. This wide scholarship made him a versatile conversationalist, and his friends will treasure the long and interesting talks they had with "Robbie." He was the perfect companion, for he could listen with understanding and patience to people who knew much less than he did, and he made them feel more intelligent by drawing out the little learning they had. He was a skilful writer with a gift for expressing himself clearly even on the most abstract or controversial subjects. So original and stimulating were his letters that they were often kept and passed round among his friends. He was a very capable musician and got much pleasure from playing in amateur orchestras and quartets. He had a quick wit and his gaiety and sparkle were the more striking because of the contrast they made with his face, which was serious and almost melancholy. His lively mind was not satisfied by any ready-made set of ideas or by doctrines backed up by tradition instead of reason. His sincerity and honesty were such that he could discuss unorthodox religious ideas with the most rigid believer without giving offence, and he never ceased the vain search for a creed that would satisfy both his rationalism and his idealism. He will be profoundly missed by everyone who knew him, and his close friends find his death leaves an emptiness which nothing can fill.

Medical Notes in Parliament

Health Service Bill: Motion for Rejection

In the names of Mr. Churchill, Mr. Eden, Mr. Richard Law, Mr. Willink, Mr. Butler, and Earl Winterton the Conservative Party in the House of Commons tabled on April 8 a motion for the rejection of the National Health Service Bill. It runs: "That this House, while wishing to establish a comprehensive health service, declines to give a second reading to a Bill which prejudices the patient's right to an independent family doctor, which retards the development of the hospital services by destroying local ownership and gravely menaces all charitable foundations by diverting to purposes other than those intended by the donors the trust funds of the voluntary hospitals; and which weakens the responsibility of local authorities without planning the health services as a whole."

"Consultation" on the Bill

Mr. DE LA BÈRE on April 4 asked whether the Prime Minister, in view of the secrecy imposed on the British Hospitals Association during their recent discussions with the Minister of Health and the misunderstandings which such secrecy engendered, would give an assurance that the Government would discontinue this practice in connexion with the introduction of further measures of legislation. Replying for Mr. Attlee Mr. HERBERT MORRISON said that in the case mentioned the Minister of Health was not consulting the British Hospitals Association as such or expecting it to commit itself to any specific proposals. He was consulting a group of individual representatives from the association in order to obtain their personal expert opinion on certain points before the Government's proposals were submitted in the proper manner to Parliament. Such a consultation was naturally confidential, and Mr. Morrison saw nothing to be deprecated in it.

Mr. DE LA BÈRE asked whether Mr. Morrison appreciated how regrettable it was that these enlightened representatives were both gagged and muzzled. He asserted that the Government always sought to move the Closure, both in Parliament and with the general public, on all matters of truth. Mr. MORRISON said that seemed to be rather a mouthful of irrelevances. These confidential discussions were started by Mr. Willink, the previous Conservative Minister of Health. If Parliament was never to permit confidential discussions prior to the introduction of a Bill, the alternative was to bang the Bill down on the Table and say to all those interested, "There you are, take it or leave it." He thought it far better to consult people.

Mr. OLIVER STANLEY: Was not this the procedure which the Minister of Health adopted in this House, and did he not, in fact, gag them by asking them to come and see him, and then paying no attention to them?

Mr. MORRISON: If consultation proceeds on broad policy prior to the introduction of a Bill, it must be confidential. The right hon. gentleman may call it gagging if he likes—that is just Conservative language—but they must be confidential. That is what it amounts to. I am perfectly sure that the right hon. gentleman, in the course of his Ministerial life, has had heaps of consultations of precisely the same type.

Demobilized Doctors and the Health Service

Mr. SOMERVILLE HASTINGS inquired on April 4 whether the Minister of Health had any statement to make regarding the employment of demobilized doctors before the National Health Service Bill came into operation. Mr. BEVAN said he would be glad to consider whether there was any statement he could make which was likely to be of assistance to doctors leaving the Forces, but it would be appropriate that any announcement should follow and not precede discussion of the principles of the National Health Service Bill by the House.

Control of Nurses

Replying on April 4 to Mr. Haydn Davies, Mr. BEVAN said that, as was announced on Dec. 13, general controls on the movement of nurses and midwives would cease to operate on June 20. It had accordingly been decided that the Mental Nurses (Employment and Offences) Orders should be revoked and cease to operate on that date. Revocation of these Orders might cause temporary difficulties in retaining staffs in some institutions, but if the Orders were not revoked the mental nursing service would, after June 20, be the only branch of nursing subject to restrictions of that kind. That would be a

grave handicap to future recruitment to the service. After full consideration the Government concluded that the balance of advantage lay in withdrawing the Orders on June 20.

A similar announcement was made in the House of Lords.

Release of Doctors

Mr. BEVAN announced on April 4 that the number of doctors released from the armed Forces since VE Day was: Navy, 1,411; R.A.F., 1,054 (in both cases to March 15); Army, 5,907 (to March 25). The numbers serving at those dates were, respectively, 1,229, 1,602, and 6,371.

Medical Care in Rural Areas

On April 4 Lieut.-Col. HARE asked Mr. Bevan to ensure that every village without a resident doctor should have a visiting doctor who would hold a surgery once a week. Mr. BEVAN said a special fund was available from which assistance could be given to insurance doctors practising in isolated rural areas for such objects. He had, however, no power of direction in this matter, nor would it in any event be practicable to make such arrangements covering every village.

Smallpox on Incoming Ships

Mr. BEVAN stated on April 2 that the number of cases of smallpox landed in this country from the ships mentioned below and the reported vaccination history of each were as follows:

Empress of Australia—1 case. Vaccinated in infancy, and several times while in the Merchant Navy, but with no take.

Duchess of Richmond—4 cases. Vaccination: (a) infancy; 1940, slight take; July, 1945, no take; (b) infancy; May, 1941, September, 1941, and September, 1944, no take; (c) infancy; July, 1945, no take; (d) March, 1942; April, 1943; August, 1945.

Georgic—No case.

Batory—1 very doubtful case. Vaccinated in infancy and frequently during service, lastly in 1945.

Orontes—1 case. Vaccinated in infancy and in January, 1946.

Service personnel from the *Duchess of Richmond* were retained under medical supervision from arrival on March 1 to March 7; and from the *Georgic* from arrival on March 2 to March 4, when it was decided that a suspected case was not a case of smallpox. Three contact cases from the *Empress of Australia* were taken to hospital.

Hospital Beds

Mr. BEVAN stated on March 28 that the number of patients in Service hospitals in Great Britain was approximately 21,300 and the number of trained nurses 1,936. The figures for civil hospitals (not including mental, mental deficiency, and maternity hospitals and institutions) were approximately 282,100 patients and 30,900 trained nurses. The number of beds reserved in civilian hospitals and institutions in England and Wales for the Emergency Hospital Scheme was approximately 53,000. No part of this total reservation was set aside exclusively for military patients, but the latest available figures showed that of these beds 15,800 were occupied by Service patients and 10,700 by civilian patients who were the responsibility of the scheme, leaving approximately 26,500 vacant emergency scheme beds, the majority of which were unstaffed. The bed reservation figures for the Emergency Hospital Scheme were under constant review. If hospital authorities found it necessary to encroach upon the emergency reservation they were at liberty to do so in agreement with the responsible medical officers of the Ministry of Health. It was hoped to release a substantial number of beds after June 1, when it was expected that the Army's needs for civilian hospital services would be limited to exceptional cases which could not be provided for in military hospitals.

Nursing Vacancies

On March 28 Mr. BEVAN said that there were approximately 28,000 vacancies notified to the Ministry of Labour and National Service on March 11 for nurses of all grades in hospitals and similar institutions in Great Britain. During the six-month period ending Feb. 28 3,239 trained nurses were released from the Forces. The number still in the Services was 8,973.

Road Accidents

Mr. STRAUSS, replying on March 25 to a debate on road accidents, said the Ministry of Transport had been anxious to reintroduce driving tests as soon as possible, but in his view their usefulness could be exaggerated. Few accidents took place as the result of action by motorists who had been only six months on the road. Most of the accidents took place through motorists who had been driving for a long time. He hoped

that driving tests could be introduced in the autumn. No decision had been made on the classes of persons to whom they should be applied.

Doctors in Austria.—Replying on March 21 to Col. Stoddart-Scott, Mr. J. B. HYNDS stated that all posts in the medical faculty of Vienna University were filled except two. The University authorities were at liberty to offer these posts to Austrian doctors in the United Kingdom, but there was no general shortage of doctors in Austria.

Disabilities in Deaf Children.—Asked on March 28 how many deaf children were suffering from epilepsy, marked mental retardation, blindness, and impaired vision, Miss ELLEN WILKINSON said she had no information of the total number of these children in England and Wales. In one special school for the deaf which catered for such children there were 48 who were educationally retarded, 6 who were blind, and 5 who were partially sighted, and a few such children were in attendance at other schools for the blind and the deaf. It was hoped to provide for a group of these children in due course in another school for the deaf. With this additional provision the needs of the whole country would be met.

Notes in Brief

Accounts of income, and expenditure of the General Medical Council and of the Branch Councils and apportionments of the amounts payable to the General Council by the Branch Councils for 1945 were presented to Parliament on March 26.

Sir Ben Smith said on March 27 that there was no prospect of his bringing soap rationing to an end at an early date, nor of his providing extra supplies.

Deafness of any type or category due to war service is accepted for pension purposes. The question of a revision of categories does not therefore arise. Approximately 15,500 compensation awards have been made to persons suffering from disablement due to aural disease or deafness arising out of the war.

Mr. Isaacs has decided to establish a number of rehabilitation centres on the lines of the Egham one in various parts of the country.

A statistical inquiry has been finished into the system of priority permits for milk. Sir Ben Smith is seeking the advice of his medical advisers on certain aspects, but Dr. Summerskill says there does not appear to be serious or widespread abuse of the issue of permits.

Universities and Colleges

UNIVERSITY OF LONDON

The following members of the medical profession have been elected Fellows of University College, London:

Arthur John Gardham, M.S., F.R.C.S., surgeon, University College Hospital; John Collis Hawksley, M.D., F.R.C.P., physician, University College Hospital; Mrs. Elfrida Lilian Gwendolen Hilton (*née* Hill), M.B., B.S., D.M.R.E., F.F.R., radiotherapist, University College Hospital; and Robin Sturtevant Pilcher, M.S., F.R.C.S., professor of surgery, University College Hospital.

UNIVERSITY OF LEEDS

The following candidates have been approved at the examinations indicated:

M.D.—C. E. Astley, H. S. Capoor, J. H. Fodden, E. Leigh, M. M. Nagley, D. Taverner (with distinction), W. Whitaker.

FINAL M.B., Ch.B.—Helen Samson (with second-class honours), C. T. H. Barrett, E. H. Batt, Yvonne Dales, N. Goldberg, H. Hanson, Enid M. Jesse, Joan N. Leedham, A. Levy, N. Mellor, Doreen E. Newland, N. H. Silvertown, Sara I. Sunson, Elizabeth M. Stokes.

The following scholarships and prizes have been awarded: *Littlewood Prize*, Audrey Gillott, R. E. Rossall. *Infirmity Scholarship*, R. E. Rossall. *Birkett Prize*, Audrey Gillott. *Waddington Prize*, Margaret J. Barker. *Hardwick Prize* and *West Riding Panel Practitioners' Prize*, Henriette Lackner. *McGill Prize*, Yvonne Dales. *Scattergood Prize*, Mary M. Matheson.

UNIVERSITY OF WALES

The following candidates for the degrees of M.B., B.Ch. at the Welsh National School of Medicine have satisfied the examiners at the examinations indicated:

HYGIENE.—Margaret E. Davies, Clare G. M. Dillon, S. T. James, M. G. Jones, N. E. H. Jones, K. P. Williams.

PATHOLOGY AND BACTERIOLOGY.—D. R. Bowen, Elizabeth B. Butler, Joan P. Ciantar, A. C. Coulthard, G. C. Davies, H. C. Davies, Janet Dean-Jones, J. A. Emanuel, G. S. Foster, H. Harrop-Griffiths, C. Harvard, C. H. L. Howells, T. R. Hunt, Eluned K. Jones, H. T. Jones, Margaret E. B. Jones, W. R. King, J. B. R. Lewis, L. T. Lewis, Constance A. M. Llewellyn, Margaret I. Morgan, V. J. Parker, F. I. Powell, Myfanwy M. G. Prethero, L. T. Rees, G. G. Richmond, Prudence K. Roberts, S. Solomon, Heather Stoddale.

MEDICINE.—T. J. Anthony, A. H. Beynon, B. L. Crystal, Norah C. Curran, D. K. L. Davies, E. D. Edwards, E. M. L. Evans, D. B. Harries, J. M. Hughes, M. G. Jones, Nest Jones, Bernice G. Lewis, J. M. Lewis, Isobel F. A. Mitchell, Margaret Owen, Barbara M. Parker, Beryl P. Roberts, K. I. Roberts, S. L. Stone, W. D. C. Thomas, D. M. Watkins.

SURGERY.—A. J. Barry, D. K. L. Davies, A. S. Jones, M. G. Jones, R. L. H. Jones, J. M. Lewis.

OBSTETRICS AND GYNÆCOLOGY.—S. T. James, Bernice G. Lewis, B. F. Richards.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

The Princess Royal paid an informal visit to the College on March 29. Her Royal Highness, who is an Honorary Fellow, inspected the war damage and the restoration work which is in progress, together with the plans for rebuilding the College. She was also shown the surviving Museum specimens being made ready for exhibition.

Surgery Lectures: An Amendment

Owing to the absence of Mr. J. B. Hunter in Jamaica on Government business, the lecture to have been delivered by him on April 24 will now be given by Mr. T. Holmes Sellors. The title of the lecture will remain the same—i.e., "Surgery of the Heart."

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At a meeting of the Faculty, with Mr. William A. Sewell, President, in the chair, George Howard Bell, M.D. (Glasgow), Leslie John Davis, M.D., F.R.C.P. (Glasgow), Thomas Ferguson, M.D., D.Sc., F.R.C.P.Ed. (Glasgow), Robert Hill, G.M., M.B., Ch.B. (Ayr), Alexander Adam Kirkland, M.B., Ch.B. (Dundee), and James Robertson Preston, M.B., Ch.B., D.P.H. (Glasgow), were admitted Fellows *qua* physician; and Thomas Hugh Crawford Barclay, M.B., Ch.B. (Glasgow), John Cunningham Liddle, M.B., Ch.B., D.L.O. (London), William Laird Milne, M.B., Ch.B. (Milngavie), and Alexander Walker Naddell, L.R.C.P.&S.Ed., L.R.F.P.S. (Glasgow), were admitted Fellows *qua* surgeon.

The Services

Air Marshal Andrew Grant, C.B., C.B.E., K.H.S., has been appointed Director-General of Medical Services, Air Ministry, in succession to Air Marshal Sir Harold E. Whittingham, K.C.B., K.B.E.

CASUALTIES IN THE MEDICAL SERVICES

Died.—Capt. P. G. Fennell, I.A.M.C.

Killed.—Capt. John Mockler, I.A.M.C.

Now officially presumed killed in action.—Capt. Archibald McLellan, R.A.M.C.

Previously reported prisoner of war, now reported died as prisoner of war.—W/Capt. M. G. Graham, R.A.M.C.

Previously reported prisoner of war, now reported missing presumed killed.—Surg. Lieut.-Cmdr. David Noel Ryalls, R.N.V.R.

Wounded.—Major F. Murray; Temp. Major I. Calvert-Wilson; Capt. H. W. Lees; W/Capt. E. D. M. Anderson, J. T. Anderson, M.C., I. H. Baum, R. D. Chalmers, J. D. Comline, G. R. Evans, M.C., R. S. Gibson, E. P. Jones, J. H. McBeath, D. R. I. Mason, D. W. Moynagh, M.C., J. M. B. Pooley, and A. C. Porteous; and W/Lieuts. J. D. Devitt and J. G. Searle, R.A.M.C.

Medical News

The annual general meeting of the Society for the Study of Inebriety will be held at the Medical Society of London (11, Chandos Street, W.) on Tuesday, April 16, at 4 p.m., when Dr. H. J. Norman will give the presidential address entitled "Discursive Thoughts on Alcohol and Drugs," and Dr. W. R. Bett will read a paper on alcoholism and crime in Ceylon.

The annual general meeting of the Food Group of the Society of Chemical Industry will be held on Wednesday, April 17, at 6.30 p.m. at the rooms of the Chemical Society, Burlington House, Piccadilly, W. It will be followed by an address by Dr. C. S. Hanes, F.R.S., on food and phylogeny. The summer meeting of the Food Group will be held in Scotland from May 30 to June 3; the honorary secretary is Mr. L. H. G. Barton, Society of Chemical Industry, 56, Victoria Street, London, S.W.1.

The meeting of the Middlesex County Medical Society arranged for to-day (Saturday, April 13) at Hillingdon County Hospital has been postponed until further notice.

The first post-war annual dinner of the University of Birmingham Medical Society will be held at the Botanical Gardens, Edgbaston, Birmingham, on Friday, June 14, at 7.30 p.m. All past and present students and members of the teaching staff are invited. Tickets 10s. 6d. (graduates) should be obtained from the secretary of the society, the Medical School, Edgbaston, Birmingham, 15. Applications should be made before May 18.

Dr. A. J. Swanton, who has been deputy coroner since 1930, was on March 28 appointed city coroner for Leeds.

Lord Woolton has accepted the office of president of the Health Congress which is to be held at Blackpool from June 3 to 7 next by the Royal Sanitary Institute. The congress will be divided into sections dealing with the following subjects, and presided over by those named: Preventive Medicine, Sir Wilson Jameson, M.D., F.R.C.P. Engineering and Architecture, Sir Reginald Stradling, D.Sc., F.R.S. Maternal and Child Health, the Marchioness of Reading. Veterinary Hygiene, Prof J G Wright, F.R.C.V.S. Food and Nutrition, Prof. S. J. Cowell, M.B., F.R.C.P. Housing and Town Planning, Mr. Norman H. Walls. There will also be conferences of medical officers of health, engineers and surveyors, sanitary inspectors, and health visitors.

Three surgeons from the Argentine are visiting this country. Prof. Egués, who comes under the British Council's auspices, holds the chair of clinical surgery in the University of Buenos Aires. Outside London he will visit Edinburgh, Manchester, Birmingham, and Oxford. Dr. Castro O'Connor, who is plastic surgeon to the Institute of Clinical Surgery, Buenos Aires, and studied with Prof. Florey at Oxford in 1932, and Dr. J. L. Curutchet, formerly surgeon to the Rawson Hospital, Buenos Aires, and surgeon director of the San Martín Hospital at Tabacal, who is specially interested in orthopaedics, are here under the auspices of the O'Connor Scholarship Scheme, but the British Council is helping with their programmes.

The Royal Medico-Psychological Association has changed the date of its May quarterly meeting; this will be held at the Retreat, York, on Friday, May 17, the council and committees meeting on the previous day. The subjects for discussion include child psychiatry and the history of the Retreat. Members who propose to attend should write without delay to Dr. A. Pool, medical superintendent of the Retreat. The annual meeting of the Association will be held at the Royal College of Physicians of Edinburgh on July 17, 18, and 19, with the president-elect, Prof. D. K. Henderson, in the chair.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales further rises occurred in the incidence of measles 270, whooping-cough 184, and scarlet fever 182, while a fall was recorded for diphtheria 58 and dysentery 43.

The rise in the notifications of measles was mainly contributed by London and Lancashire, with increases of 167 and 69, while the only decrease of any size was Norfolk 43. The feature of recent measles returns is the relatively large incidence in London, where one-third of the total cases have appeared during the past three weeks.

A small general rise in scarlet fever was reported, the only large local increase being Glamorganshire 33. The largest variations in the local trends of whooping-cough were an increase in Hertfordshire 62 and a decrease in Essex 33. Notifications of diphtheria fell in Yorkshire West Riding 22 and London II, but rose in Northumberland 11.

An outbreak of dysentery involving 24 persons was reported from Staffordshire, Stoke-on-Trent C.B. Of the 104 cases in Lancashire, 53 were from the outbreak in Chorley M.B. Other large totals were those of London 26, Leicestershire 25, Warwickshire 20, Middlesex 14, Essex 13.

In Scotland an increase of 26 in cerebrospinal fever resulted in the largest weekly total of recent months. Diphtheria returned to its recent level with an increase of 60 cases. Rises were also reported for measles 35, scarlet fever 28, and dysentery 25. The largest returns for dysentery were Glasgow 16, Edinburgh 11, and Renfrew County 13.

In Eire there were increases in primary pneumonia 30, whooping-cough 23, diarrhoea and enteritis 15; and decreases in scarlet fever 19, and diphtheria 7.

In Northern Ireland the only change was an increase of 23 in scarlet fever, due to isolated cases in several areas.

Statistical Review, 1941

The statistical review of the Registrar-General, which, except for a limited number of copies for 1939 and 1940, has not been published during the war, makes its reappearance with Part I (Medical) for 1941. Two important changes have been introduced. The system of using the 1901 population as a basis of standardized death rates is to be replaced by a new procedure for standardizing mortality for comparative purposes. For the first time the actual number of births occurring in a calendar year are shown, instead of those which were registered in that year.

Week Ending March 30

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,393, whooping-cough 2,092, diphtheria 478, measles 2,282, acute pneumonia 1,079, cerebrospinal fever 74, dysentery 356, paratyphoid fever 4, typhoid fever 8, smallpox 2. Deaths from influenza in the large towns numbered 50.

No 12

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended March 23

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Rate per 1,000 total births (including stillborn)

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ One case removed from a troopship.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Atiology Westcent*, London. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent*, London.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Penicillin for Styes

Q.—*An otherwise healthy child aged 2 suffers from recurrent styes. No local treatment has been applied except penicillin cream to one particularly severe sty, and this was effective. I am advised that as the infection is apparently staphylococcal a single penicillin injection would probably clear up the condition. Is this correct?*

A.—A single injection of penicillin, however large the dose, will not clear up anything (with the possible exception of gonorrhoea). For the treatment of any staphylococcal infection intramuscular injections would have to be continued three-hourly day and night for at least several days. Such treatment is certainly not indicated in the case described, both because it is extravagant and troublesome and because it might well fail. Blepharitis calls for local treatment, and the application of penicillin cream, continued patiently for a week whether any styes appear or not, will probably eradicate the infection.

Asthma at Menopause Age

Q.—*A female patient aged 43 was diagnosed some nine months ago as a case of spastic bronchitis. The patient's chest condition this winter has appeared even more "moist" than last winter. Her breathing, especially at night, is noisy, and there is some dyspnoea on exertion. She does not smoke. I note a reference to menopausal rhinitis in the issue of March 2 (p. 341). May an approaching menopause in my patient, though there seems little definite evidence of this, have any bearing on her condition?*

A.—The history of noisy breathing at night is suggestive of asthma; if the sputum is purulent it is probable that a bronchial infection is an important factor. The menopause is not likely to be the cause of the condition. The patient should be investigated by skin tests in regard to sensitivity to dust, feathers, etc. It might be worth while trying the effect of removing all feathers and dust, etc., from the bedroom. In brief, the full investigation of an asthmatic should be undertaken.

Rhinitis after Alcohol

Q.—*For nearly ten years I have suffered from allergic rhinitis with recurrent polyp formation. Half an hour after taking any wine, spirits, or beer, acute rhinitis develops. Is it possible to desensitize myself against this? And if so, what method should I use?*

A.—Since the allergic rhinitis occurs with different varieties of alcohol, the offending agent must be the alcohol and not the grain or fruit from which the particular variety of alcohol is made. It is unlikely that the reaction is allergic in the narrow sense, for there is no evidence that alcohol can act as a haptene or change the body proteins in such a way as to give rise to drug allergy. It is much more likely that the alcohol dilates the vessels of the polypi and nasal mucosa, and this in turn gives rise to a reflex rhinorrhoea. It would not be possible to desensitize, as vasodilatation is the normal physiological response to alcohol. Inhalation of amphetamine ("benzedrine") or carbon dioxide (Bray, G. W., *Recent Advances in Allergy*, 3rd edit., 1937, p. 309) might give relief. It is also believed that alcohol may pave the way for allergy by increasing

the permeability of the gastro-intestinal mucosa to proteins ingested at the same time. For this there would seem no remedy except abstinence.

Arsenic and Horse-nettle

Q.—*An epileptic woman aged 27 has been taking for nine years 1½ oz. (14 ml.) of the following prescription, three times a day: liq. arsenicalis 1 dr. (3.5 ml.), pot. brom. 5 dr. (17.5 ml.), sod. bicarb. 4 dr. (14 ml.), tr. belladonnae 2 dr. (7 ml.), ext. Solanii carolinense 14 dr. (49 ml.), aqua ad 12 oz. (340 ml.). What is ext. Solanii carolinense? Why does she not develop arsenical poisoning?*

A.—Ext. *Solanii carolinense* is an extract of the American horse-nettle, which grows in the Southern States, and presumably in Carolina. The liquid extract (1 in 1) has been employed in epilepsy, the dose being 15 to 60 min. (0.9 to 3.5 ml.). It contains a toxic principle, solatubine, which seems to be the same as the saponin-like substance, solanine, found in various species of *Solanum*. There is also said to be an organic acid, solanic acid. The American horse-nettle is sometimes called "apple of Sodom."

The second question, why the patient does not develop arsenical poisoning, is answered by saying that the patient does not receive enough arsenic trioxide for that to happen. Calculation shows that her daily intake is not more than 5 mg., or about 1/12 gr., and this is an amount likely to develop resistance to arsenic when taken regularly. The single toxic dose is 100 mg., or 1½ gr.

Death in an Ambulance

Q.—*When a patient dies while being transported by ambulance what is the correct procedure?*

A.—If a patient should die while being transported by ambulance the driver should take the body to the nearest hospital, or to the hospital to which the patient was travelling, for verification of the fact of death. The hospital may or may not take the body into their mortuary, or may direct the driver to the city mortuary. It is the duty of the driver to notify the police, who in turn will notify the coroner, if in England, or the fiscal, if in Scotland, who will take the necessary steps concerning the disposal of the body. If the body is taken to a hospital mortuary it is customary for the hospital authority to notify the police.

Rectal Prolapse

Q.—*What is the best treatment for rectal prolapse with a large sphincter and moderately severe pruritus ani? Cauterization and injections of sclerosing fluid have been tried with no success.*

A.—If the prolapse is large and very troublesome and thorough palliative treatment has been a failure, then the patient should be submitted to operation. The most favoured operation at present is simple amputation of the prolapse from below with suture of the divided ends of the bowel. Operation gives the most satisfactory results and does not carry any risk.

Infection by Epidermophyton of Sabouraud

Q.—*A patient has had for twenty years or more a dry, scaly condition between the fifth and fourth toes, worse in the summer, with occasional cracks of the skin which are not very painful. What is the condition and how can it be cured?*

A.—The condition as described above is probably caused by infection with the epidermophyton of Sabouraud. The diagnosis can be verified by microscopical examination of the epidermis. This is a useful preliminary to treatment, since all interdigital lesions are not necessarily due to a ringworm fungus. In spite of the introduction of many new applications, Whitfield's ointment and Castellani's fuchsin paint are still the best topical applications. The long history in this case is against the prospect of easy or rapid cure.

Splenectomy

Q.—*What are the indications for splenectomy, and what is the rationale in each instance for this line of therapy?*

A.—The only absolute indication for splenectomy is rupture of the spleen; in more medical conditions the recommendation

of splenectomy usually has to be qualified. It should also be noted that with modern methods of investigation and treatment, ensuring accurate pre-operative diagnosis and adequate preparation by transfusion, etc. the risk of operation has been greatly diminished.

Splenectomy practically always arrests the symptoms of familial acholuric jaundice, and should be recommended when ever the anaemia, jaundice or cholelithiasis is bad enough to bring the patient under medical attention. Splenectomy is of no value in other congenital haemolytic anaemias such as sickle-cell anaemia and Mediterranean anaemia. In acquired haemolytic anaemia the effect of splenectomy is always problematical and the more the blood picture departs from that of acholuric jaundice the less likely the operation is to be successful. Patients with frank megalocytosis hardly ever do well. In acute haemolytic anaemia not responding to transfusion the patient should always be given the chance of benefiting from splenectomy, but not too much should be promised.

Splenectomy is the only effective remedy for thrombocytopenic purpura, but there is a small proportion of failures and the relief is not always permanent. As thrombocytopenic purpura may remit spontaneously, splenectomy is not usually advised unless the purpura is established and chronic, or the symptoms are urgent and endanger life.

The third commonest indication for splenectomy is splenic anaemia. In most if not all, cases of splenic anaemia the disease begins in the liver and the splenomegaly is merely a symptom of portal hypertension. Operation is justifiable only if the spleen itself is producing ill effects such as local pain and dragging thrombocytopenia, or extreme leucopenia. Splenectomy cannot be expected to prevent haematemesis in splenic anaemia, as this is usually due to oesophageal varices. Similar considerations govern the removal of the spleen in Gaucher's disease, sarcoidosis and some of the Hodgkin's group of reticulososes. It is legitimate to remove the spleen when it is acting as a painful tumour or producing severe leucopenia or thrombocytopenia.

The only absolute contraindications to splenectomy are osteoclerosis and myelofibrosis, where the spleen enlarges to take over the functions of the bone marrow, though it must be confessed that the enlargement is often sadly excessive and unproductive.

Pelvic Measurements of Western Women

Q.—*Mary W. Hamilton in the 'Fortnightly Review' (Dec 1945) states that the pelvic measurements of Western women are getting smaller with each generation particularly in the towns. Can you tell me whether this assertion is founded on any accurate observations?*

A.—With the development of civilization and particularly the growth of large industrial centres, with the shift of population from the country to the towns, there can be little doubt that the incidence of contracted pelvis increased. This was mainly due to rickets, or at least was a manifestation of poor living conditions, overcrowding, inadequate diet, etc. The difference between urban and rural dwellers is still to be seen in some areas. Thus H. R. MacLennan (*J. Obstet. Gynaec. Brit. Emp.*, 1937, 44, 245) reported that, whereas contracted pelvis—mainly due to rickets—was very prevalent in Glasgow and other industrial areas it was rare in the country areas of Scotland. The effect of civilization, or rather unhealthy living conditions, is also shown by the frequency of contracted pelvis among negroes in American cities.

Nevertheless, the living conditions and the general health of even the poorer classes in the Western countries are rapidly improving, and have been improving for a few generations. The general physique of women is better, rickets is becoming comparatively rare and contracted pelvis is less common. Although a few "black spots" remain, this is true even for large congested areas, such as London. We no longer have to deal with cases of gross pelvic contraction—such as confronted obstetricians at the end of the last century. The size of the pelvis is largely a reflection of the general physique of a woman. With the improvement which has come about during the last few decades it would be difficult to substantiate the statement quoted above.

The article mentioned is not available for study, but perhaps the author was referring to characteristics other than the size

of the pelvis. It is alleged, as a result of comparison between the ease of labour in primitive and in Western peoples, that the drift from "Nature" has affected the shape of the pelvis and the mobility of its joints. The unnatural postures and work of modern women are said to make the inlet less round. However, these comparisons are difficult to interpret, for other factors such as the size of the foetal head in different races, the efficiency of the uterus and the psychological approach to labour enter into consideration. This aspect of the case is dealt with by Kathleen Vaughan in *Safe Childbirth* (1937, Looe—Bailliere, Tindall and Cox).

New Antibiotics

Q.—*The bacteriological and biochemical literature is full of the results of experimental work in the field of antibiotics. Are there any antibiotic substances other than the sulphoamides and penicillin worthy of a place in routine clinical therapeutics? Must our specific therapeutic attacks end where we have proved an infection to be caused by sulphoran-de and penicillin resistant organisms?*

A.—The answer to the first part of this question is Yes—tyrothricin and streptomycin. The former is on the market, and it is to be hoped that the latter will eventually be available in England. At present supplies of streptomycin are very meagre even in the U.S.A., which is the country of its origin. There are several other antibiotics which give promise of therapeutic value for particular purposes. The numerous papers to which the questioner refers are chiefly accounts of early stages in the work which has to be done before such a substance can establish itself in therapeutics. To show that it has an antimicrobial action is only a beginning; it is then necessary to study its toxicity and other features of its behaviour in the body. It may also be a long process to work out a method by which a substance can be adequately purified. Finally, the manufacturer has to face the hazards and difficulties of production on a commercial scale, and only after this can adequate clinical trial be begun. It is five years since the outstanding therapeutic properties of penicillin were recognized yet even now supplies of it are limited. Progress even in times of peace with further antibiotics which merely extend the scope of such treatment cannot be expected to be much more rapid.

"BAL"

Q.—*Now that BAL is off the secret list I would like to know if it was issued to any of our Services or A.R.P. during the war. Some American doctors told me that it had been issued to American troops.*

A.—BAL was issued to the medical services and to the Ministry of Health for hospital use. The ointment was never a personal issue to British Forces, though production of personal outfits was in hand at the cessation of hostilities. British troops were, however, provided with eye shields which, like the respirator, afford complete protection to the eyes not only against lewisite but also against other gases in the form of spray or droplets. BAL was a personal issue to American troops in the Pacific area and S.E. Asia but eye shields were not used by the U.S.A.

Altitude and High Blood Pressure

Q.—*What effect has high altitude or blood pressure? Should patients suffering from high blood pressure leave such altitudes—for example in Iraq?*

A.—For permanent residence altitudes below 5,000 ft. (1,524 m.) have very little effect on the circulatory system. From 5,000 to 10,000 ft. (1,524 to 3,048 m.) circulatory effects begin to appear, and from 10,000 to 15,000 ft. (3,048 to 4,572 m.)—e.g., in Chile and Bolivia—the circulatory effects become important and a number of special conditions attributable to altitude are found among the higher age groups of the population—e.g., Monge's disease.

I think the questioner's interest is undoubtedly in the 5,000 to 10,000 ft. altitudes. Here there will be an increased red cell blood count, leading to increased blood viscosity, this adds considerably to the work of the heart and is often accompanied by a rise in blood pressure, in fit individuals this should not amount to more than 15 mm. Hg. There is also a loss of buffer substances from the blood, which makes respiration very unstable to exercise. Altitude is an added stress to high

blood pressure, and altitudes above 10,000 ft. (3,048 m.) are undesirable in such cases. Altitudes less than 5,000 ft. (1,524 m.) are unlikely to be a serious factor aggravating the condition. Between 5,000 and 10,000 ft. the morning basal resting pulse should be a guide to indicate whether the condition is sufficiently serious to warrant the patient going to a lower altitude. If this is more than 20 beats per minute above the normal expected at sea level for a patient of the build, age, and habits of the case under consideration, this should be grounds for going to a lower altitude if possible.

INCOME TAX

Replacement of Instruments and Books

A. C., who is in the public health service, has been refused a request for an allowance of the cost of replacing out-of-date medical textbooks.

* The expenses rule applicable to the earnings of employment is a stringent one. To be allowable the expenses under Schedule E must be incurred "wholly, exclusively, and necessarily in the performance of the duties" of the employment. The difficulty in such a case as this arises out of the word "necessary." The courts have held that expenses of the kind specified cannot be regarded as necessary unless the maintenance of the asset—i.e., the medical library—is required as a condition of the employment.

Newcomer to the United Kingdom

R. W. came to this country in February, 1945, to take up a salaried appointment. Should he not be taxed for the period to April 5, 1945, as if the income for that period were the income for a full year?

* Yes—i.e., the full year's "personal" and any other allowances should be set against the income for the period in question. If tax has been paid on the basis that only a proportion of the allowances was given, R. W. is advised to take the matter up with the inspector of taxes. (It is assumed that R. W. ranks as a British resident for 1944-5; that carries with it liability to tax on income arising abroad but received in this country.)

Pensioner: Deduction of Tax

G. C. B. has two sources of income falling under "pay-as-you-earn," and tax is deducted at 10s. in the £ from the income arising from one of the two sources. Can this be correct?

* Each taxpayer is entitled to certain allowances—the "personal allowance," the "relief in respect of earned income," and so on. If all these allowances are given from one source of income, the fact that other sources are taxed at the standard rate would be correct. G. C. B. should have received a "coding notice" showing what allowances have been made in connexion with that source of income which is taxed at less than 10s. in the £; and reference to that notice should show whether he is receiving *all* his allowances from that source.

Whether within "Pay-as-you-earn"

"D. X." has returned to his partner on demobilization on the following terms: "D. X." receives a basic salary plus a proportion of the profits. He pays his own expenses for car, telephone, surgery, and maid. Does he come under "pay-as-you-earn"?

* On these facts it is assumed that "D. X." works in the practice as an employee and not as a partner, and on that assumption he is within "pay-as-you-earn." His "coding" should take into account the probable amount of his expenses, as well as the personal allowances he can claim. It is advisable to get in touch with the local tax office suggesting that if they insist on the application of "pay-as-you-earn" in these circumstances, then an allowance for expenses amounting to a specified sum (giving some details) should be incorporated in the coding.

Additional Emoluments: Expenses

"ORTHOPOD" is a specialist in a Service hospital but looks after some civilian patients and receives money for so doing from the county council. Can he deduct expenses incurred in running a car, subscribing to professional journals, etc.?

* If the work done for the county council is the result of an appointment under the council, the fees received would presumably be emoluments of an employment assessable under Schedule E, and these expenses would not be allowable. That is probably the case; but if "Orthopod" can persuade the local tax authorities that the fees are of such a nature that they are chargeable under Schedule D, then he can claim a reasonable expenditure on professional journals. If the car is used (apart from private purposes) only, or almost exclusively, for travelling between his residence and the hospital the expense is not allowable under either Schedule D or Schedule E.

LETTERS, NOTES, ETC.

Interstitial Mastitis

Mr. JAMES PHILLIPS (Bradford) writes: With reference to the question and answer on this subject (March 23, p. 458) may I suggest that the advice to treat by "masterly inactivity" a patient who has an "area of typical interstitial mastitis" in the left upper quadrant of a breast is fraught with danger? During a long surgical life it has been my misfortune to have to deal with quite a number of cases in which the result of acting in this way has been the loss of the patient's life. In one instance the victim was a hospital matron and the surgeon one of her "chiefs." I well remember an early morning visit from a doctor friend who burst into my consulting room and exclaimed, "Phillips, I have killed my wife!" He went on to explain that two years earlier he had been asked to look at his wife's breast; had decided that her condition was mastitis and told her that there was nothing to worry about. Of course the patient who is given this verdict must either accept it unquestioningly and forget about her symptoms or else wonder whether there can possibly be the beginning there of a malignant growth. The doctor's wife, having complete confidence in her husband's ability, was able to adopt the first alternative and only on that morning had she casually remarked that the condition of the breast was altering. On examination a fully developed cancer with evident metastases was disclosed. Had this patient been less certain of the correctness of her husband's verdict or had he suggested to her that she should be "kept under periodic observation in view of the possibility of a malignant change" it does not require a vivid imagination to picture the ever-present—though largely subconscious—awareness that some day, instead of the "no need to worry" verdict, there might be an intimation that an extensive operation was required in order to deal with a condition in which the prospects of cure were far from certain. Contrast such a patient's mental state with that of a patient from whom I removed a breast for simple mastitis and who, whenever I see her, beams and tells me that the operation removed from her mind a never-entirely-absent dread lest a cancer was going to develop in her breast. At the age of 46 at least 3 out of 4 "indurations" in the breast, in my experience, prove to be malignant.

Proctalgia Fugax

Dr. E. GALLOP (London, S.W.1) writes: I have sometimes thought that this condition could be cured by a local anaesthetization of the rectum, but I have not seen a case for years and I have had no opportunity of trying. Perhaps one of your contributors will. The procedure is simple. A suppository of novocain, or one of its many analogues which a pharmacist can easily dispense, is pushed well into the rectum. I should expect the pain quickly to disappear and recurrences to be infrequent. If there is one it could be treated in the same way, and I fancy there would soon be an end to them.

Nicotinic Acid Amide in Diabetes

Dr. W. GORDON writes to say that his letter on this subject published in the *Journal* of Feb. 9, 1946 (p. 218), brought him several replies. He was then in the course of moving house and the letters have been lost. If his correspondents will send him their addresses again to 49, St. Margaret Street, Rochester, Kent, he will immediately reply.

The Source of a Quotation

Dr. A. F. FOSTER-CARTER (Frimley) writes: The views expressed by Dr. Clifford Allen (March 23, p. 449) are so admirable that I risk a charge of pedantry by drawing attention to a minor inaccuracy. However, I would like to point out that Isaac Newton was not the author of the remark "There, but for the grace of God, etc." The *Dictionary of National Biography* ascribes the saying to John Bradford (1510?-1555) on seeing some criminals being taken to execution. It has also been attributed, but probably wrongly, to Richard Baxter (1615-1691), on seeing a drunkard in a ditch.

Long Run of B.M.J. for Disposal

Dr. R. S. CREED, New College, Oxford, will give, in return for cost of packing and transport, an unbound set of the *Journal*, believed complete, from July, 1923, to December, 1945, to a library or institution requiring it. Applications should be sent to him as soon as possible.

New Year Honours

By an oversight the name of Col. Charles Girdlestone Terrell, M.B., Ch.B., lately Member of the Assam Legislative Assembly, Medical Officer, Indian Tea Association, Assam, was omitted from the Medical New Year Honours published in the *Journal* of Jan. 12 (p. 60). He was appointed O.B.E. (Civil Division).

Another omission from our New Year Honours List has been brought to our notice. Squad. Ldr. (then Fl. Lieut.) Geoffrey Hugh Templeman, M.B., Ch.B., R.A.F.V.R., was appointed M.B.E. (Military Division).

LONDON SATURDAY APRIL 20 1946

IRITIS IN THE RHEUMATIC AFFECTIONS

BY

ARNOLD SORSBY, M.D., F.R.C.S.

Research Professor in Ophthalmology Royal College of Surgeons and Royal Eye Hospital

AND

A. GORMAZ, M.D.

Assistant Clinica Oftalmologica Hospital Salvador Santiago Chile

The designation of 'rheumatic iritis' has almost followed 'scrofulous ophthalmia' into oblivion. In an attempt to assess the frequency of iritis in the rheumatic affections 815 patients suffering from various forms of "rheumatism" were examined for evidence of active or past iritis. As these patients were seen at clinics for the treatment of rheumatic affections or in the wards of general hospitals slit lamp examination could not be carried out and only exceptionally was a mydriatic used. The eyes were inspected through a loupe under focal illumination, posterior synechiae or inflammatory pigment deposit were taken as evidence of past iritis. Evidence of iritis was also sought in a control series of in patients in the general wards. As it is possible that there may be a sex difference in the incidence of iritis—as there undoubtedly is in some of the rheumatic affections—the findings are best considered for the two sexes separately.

significant (Chance 1/21, but if deviation which is in the expected direction is allowed for the chance is 1/42). In both men and women, age—assuming that with increasing age there is an increase in the tendency toward iritis in the general population—would affect the computations only slightly.

Spondylus Arthropoietica—The 8 cases observed in women showed no instance of iritis, while the 45 men had three with iritis. This incidence in men is significant when compared with the control series (Chance 1/56, without allowing for direction the effect of age would increase significance, as the group with ankylosing spondylitis is younger than the control group. Similarly, because of the lower incidence of iritis in the female

Frequency of Iritis in a Series of 815 Cases of Rheumatic Affection

The following summary table based on Tables I and II brings out the salient findings

Incidence of Iritis in 815 Cases of Different Forms of Rheumatic Affection

	Male		Female		Total	
	No of Cases	No Showing Iritis	No of Cases	No Showing Iritis	No of Cases	No Showing Iritis
Rheumatoid arthritis	68	3	264	12	332	15
Acute and subacute rheumatic fever	57	—	90	—	147	—
Still's disease	3	—	4	—	7	—
Fibrositis	25	—	65	—	90	—
Osteoarthritis	31	—	92	3	123	3
Infective arthritis	4	—	7	—	11	—
Spondylitis ankylopoietica	45	3	8	—	53	3
Gout	5	—	8	—	13	—
Bursitis, capsulitis, and allied conditions	6	—	14	—	20	—
Scatica	5	—	—	—	5	—
Indefinite conditions	6	—	8	—	14	—
Total	255	—	560	—	815	—

These findings suggest that the only three conditions that call for consideration are rheumatoid arthritis, spondylitis ankylopoietica, and osteoarthritis.

Rheumatoid Arthritis—The occurrence of 12 cases of iritis in 264 women with rheumatoid arthritis when compared with the one case in the control series of 316 (Table II) is statistically significant. The chance is somewhat less than 1/1000 that one would draw, from a homogeneous population having the pooled frequency of the two samples, two samples differing by this amount or more. In contrast the occurrence of three cases of iritis in 68 men with rheumatoid arthritis (Table I) is just

control group the significance becomes enhanced when the male and female cases are considered together.)

Osteoarthritis.—Of the total of 123 cases 92 were females and 31 males. The three instances of iritis observed were all in women (of whom one was suffering from long-standing diabetes). Statistically, the incidence of iritis in this group is significant as compared with the control group of women, there being 27 chances to 1 against such an incidence as a chance phenomenon. The odds become reduced to 14 to 1—and therefore non-significant—if the total of 123 cases of osteoarthritis in the two sexes is regarded as one group showing three cases of iritis.

Type of Iritis Observed

Iritis in the Control Cases (Tables I and II)

The three men (in a series of 379) who showed iritis were 49, 55, and 72 years of age respectively. The first patient was dying from carcinoma of the lung; in the second the Wassermann reaction was positive; both these patients showed iritis in both eyes. In the man aged 72 the iritis was confined to the right eye and the patient was suffering from haematuria. The one woman (in a series of 316 controls) who showed iritis suffered from indefinite symptoms, and the inflammation was confined to the right eye. In none of these patients was the iritis active.

Iritis in the Patients with Rheumatic Affections (Tables I and II)

Rheumatoid Arthritis.—In a total of 332 cases with rheumatoid arthritis (264 women and 68 men) there were 15 patients showing iritis. The ages of these patients ranged between 23 and 82 years. In only one case was the iritis acute (in a woman aged 37), and in only three cases was the condition bilateral (in a woman aged 49, and in two men aged 23 and 65). In three patients there was a possibility of an aetiological factor other than rheumatoid arthritis. One woman aged 43 gave a history of iritis in the left eye at the age of 34 following an attack of mumps. She had been suffering from rheumatoid arthritis since the age of 23, and the attack of mumps precipitated not only the iritis but a considerable flare-up of rheumatoid arthritis. In another woman, aged 41, there had been repeated attacks of iritis in the left eye; she was suffering from rheumatoid arthritis confined to the right hip, and had previously had tuberculosis of that joint. There was nothing in the appearance of the iris reaction to suggest tuberculosis. In a man aged 65 there was a history of bilateral iritis which came on at the age of 38, after he had received an injection of antidyentery serum in the Army in 1918. There was a simultaneous reaction in the joints, and he had been told that he was suffering from serum arthritis and iritis. The second attack of iritis, confined to the left eye, occurred at the age of 40. Some years later—probably as long as ten years after—he showed evidence of rheumatoid arthritis. Now, at the age of 65, he has rheumatoid arthritis confined to the smaller joints.

In only two of the 15 cases was the iritis severe. In the youngest patient, a man aged 23, the rheumatoid arthritis was exceptionally severe. It had begun at the age of 15, and iritis had developed at 19. Now, at the age of 23, he is bedridden and little more than an ossified skeleton, as there is severe involvement of the spine in addition to the other joints. He has no perception of light and the tension is -2 in each eye, the eyes having shrunk through repeated attacks of severe plastic iridocyclitis. In the second patient, a woman aged 49, severe rheumatoid arthritis set in at the age of 20, but the eye trouble appears to have come on before then, and to have relapsed frequently. She is certifiably blind from chronic iridocyclitis. The striking features in the remaining 13 cases are the unilateral distribution of the iritis and its mildness. In five of these 13 cases the patient had experienced more than one attack of iritis, but none of them showed any evidence of cyclitis.

Though it is difficult to be emphatic on this point, because the histories were not always reliable, it appears that with one possible exception the iritis did not precede the development of rheumatoid arthritis, and the impression was gained that iritis is more apt to develop in long-standing cases than in cases of shorter duration. Though the two most severe cases of iritis (or rather iridocyclitis) occurred in patients severely affected,

the severity of the condition, as distinct from duration, did not seem to be directly related to the tendency towards iritis.

Ankylosing Spondylarthritis.—The three cases of iritis observed all occurred in men, their ages being 26, 35, and 38 years, respectively. In the youngest of these patients an attack of iritis in the left eye had occurred at the age of 15. The second attack developed three years later, and subsequently, at the age of 20, the first signs of ankylosing spondylitis developed. He has since had one further attack of iritis, also confined to the left eye. In the second patient there was a history of vague polyarthritis at the age of 23. His condition had then been diagnosed as rheumatic fever. His first and only attack of iritis occurred at the age of 28. This was followed by a flare-up in the joint condition, which still presented difficulty in diagnosis. It was not until the age of 34 that a definite diagnosis of ankylosing spondylitis involving hands and feet was made. In the third patient there had been a well-established ankylosing spondylitis for some years when iritis developed in the right eye at the age of 35, and in the left eye two years later. In none of these patients was there any evidence of ciliary involvement.

In these three patients the iritis was therefore a pointing sign in one case. Their spondylitis was of moderate severity, and in none was there any evidence of gonococcal infection. Some of the remaining patients with ankylosing spondylitis who did not show iritis were affected as severely as, or more severely than, these three men.

Osteoarthritis.—Iritis was observed in three of the 92 women with osteoarthritis. Their ages were 52, 73, and 80 years. All the three patients had unilateral iritis, and in one case—the patient aged 73—there was a history of long-standing diabetes. In no case was the iritis severe or associated with a cyclitis.

Incidental Ocular Findings

Among the patients with rheumatoid arthritis the following apparently incidental ocular findings were noted: senile cataract, four times; loss of eye through accident, three times; glaucoma, twice; and one instance each of Argyll Robertson pupil, rosacea keratitis, filamentary keratitis, mustard-gas keratitis, interstitial keratitis, corneal opacity, and vascularized nodule on the cornea. The osteoarthritis group showed three cases of cataract, while one of the patients with Still's disease had a leucoma. Congenital cataract was seen once among children with rheumatic fever and once among the patients suffering from fibrositis.

Review of Literature

Spondylarthritis Ankylopoietica

The monograph literature on spondylarthritis ankylopoietica speaks of the occurrence of iritis in the course of the affection as an established fact. Thus Ehrlich (1930) mentions that 65 instances of iritis occurred in a series of 753 patients with spinal-column affections (of which 493 were cases of spondylitis deformans and 260 [and possibly only 152] of spondylitis ankylopoietica). Krebs (1938) likewise implies that iritis is a not uncommon association of spondylarthritis ankylopoietica, and instances the case of a young ophthalmologist who developed iritis and choroiditis some few years before showing the signs of spondylarthritis. Gilbert Scott (1942) notes that there were 20 cases of iritis in "some 300" patients with ankylosing spondylitis. References in the same strain abound in the earlier literature. Thus Wehrsig in 1910 stressed the "surprising frequency" of iritis in "Wirbelsäuelungsteifung," whilst isolated instances are noted in a number of case reports (Leri; Fraenkel; Siven; Anschütz). More recently Fischer and Vontz (1932) noted the occurrence of iritis in three of their 100 patients, while Wolff (1935) observed it six times in 15 cases.

These general observations were considerably clarified in 1933 by the simultaneous publications of Heuser, Marbaix, Kunz, and Teschendorf.

1. Heuser.—In recording a case of bilateral severe iridocyclitis with secondary glaucoma Heuser drew attention to the associated spondylarthritis ankylopoietica (which he regarded as gonococcal in origin) and also to the incidental observations of orthopaedic surgeons as to the association of the two affections.

2 Marbaix—This observer likewise stressed the association of the two affections in a patient under his care. Marbaix's patient, in contrast to Heuser's, became blind as did the patients of Van Lint (1933) and of L. Coppez (1933) who added their case reports to those of Marbaix.

3 Kunz—A more detailed study came from Kunz. On routine examination two patients with 'rheumatic iritis' were found to suffer from ankylosing spondylitis. Other cases of possible 'rheumatic iritis' were then systematically x-rayed for evidence of the vertebral lesion and five more were discovered. Of these seven cases five showed active iritis and two evidence of old iritis and they constituted 'about half the number of 'rheumatic iritis' cases seen during the few months in which they were collected. There was only one woman in this group of seven. The iritis itself was either mild (in one case) or led to seclusion of the pupil (in three cases). In no instance was there any cyclitis. As for the spondylitis, in two cases it was obvious clinically, while in two more there was only x-ray evidence of the affection. The iritis seemed to coincide with the onset of the spondylitis in 'some cases' but mostly came on later—sometimes after many years. Many long-standing cases of ankylosing spondylitis showed no evidence of iritis. Kunz added another case to his series in 1935.

4 Teschendorf—This observer, a radiologist, collaborated with Kunz, and his account includes two additional cases. He stresses that in six of the nine cases the x-ray picture showed the typical bamboo spine, though three of these patients were not conscious of the spinal-column lesion.

The ophthalmological literature of the subsequent years contains a number of case reports.

(a) Kraupa (1933), in recording four cases, holds that the iritis reaction—which did not tend to lead to synechiae—suggests a gonococcal origin of both the affections.

(b) Smaltno (1934) added two cases—one showing acute iritis with hypopyon and the other recurrent iritis. He stressed the tendency to recurrences, and believed these to be part of the clinical picture of ankylosing spondylitis, as they came during exacerbations of the spinal-column affection.

(c) Strelb (1935) reported a case in which both the iritis and the ankylosing spondylitis responded well to operation on the parathyroids—a therapeutic procedure advocated some years ago by Opin.

(d) Schley (1935, 1937)—Of 105 patients with iritis 32 showed a localized reaction ('tuberculous or syphilitic') and 73 a diffuse superficial reaction ('rheumatic iritis'). There were no spinal column lesions in the first group, but only 23 of the 73 in the second group showed normal x-ray pictures of the vertebral column, in 10 ankylosing spondylitis was seen, and in the remaining 40 spondylosis deformans—and in none of these 40 cases was the blood sedimentation rate raised or was there other evidence of an inflammatory origin of the spinal-column lesion.

(e) Ascher (1936), in reporting four cases and noting a fifth under the care of a colleague (Ludwig) gives a survey of the 27 cases reported up to then by oculists. All but one were men. Of 11 patients whose occupation was known, only two were manual labourers. Of 24 whose ages were known, the spondylitis set in early in four instances (one instance at each of the ages of 7, 11, 19, and 20 years). The iritis was noted as mild in five instances, but there were also three bilateral and two unilateral cases of secondary glaucoma: four patients lost the sight of both eyes and one patient of one eye.

(f) Babel (1940) notes iritis running a mild course in a case of ankylosing spondylitis.

(g) Novoa Recio (1941) stresses the value of gold therapy for the iritis no less than for the ankylosing spondylitis.

(h) Franceschetti and Brocher (1944) note two illustrative cases—one of acute iritis in ankylosing spondylitis of gonococcal origin and the other of recurrent unilateral iridocyclitis with hypopyon in a patient with a non-specific ankylosing spondylarthritis. They also quote Mylius (1942) as observing a severe course of iridocyclitis as well as mild cases and as claiming as high an incidence of iritis as 50%.

Rheumatoid Arthritis

There is little concrete evidence as to the occurrence or frequency of iritis in rheumatoid arthritis. An early observation by Burt (1908) drawing attention to recurrent acute iritis in a case of rheumatoid arthritis does not seem to have been followed by other reports. Berens, Rothbard and Angevine (1942) found uveitis in two out of 83 patients with rheumatoid arthritis. They do not speak of iritis exclusively. 'To make certain that only true cases of uveitis were reported, it was necessary that keratic precipitates, cells in the anterior chamber, and other clinical signs be present'. Bauer, as quoted by these observers, found uveitis in seven out of 150 patients with rheumatoid arthritis. Cecil and Angevine are also quoted as observing three instances of uveitis in 200 cases. Dawson

(1935) speaks of having seen a number of cases of iritis in rheumatoid arthritis, four of which were particularly intractable, and two of them ended in blindness. The occurrence of iritis in rheumatoid arthritis is also indicated by Novoa-Recio (1941) and by Franceschetti and Brocher (1944).

Rheumatic Fever

The monograph literature gives iritis as an occasional occurrence in rheumatic fever (Coburn, 1931, Wilson, 1940). Coburn reports it as having occurred once in a series of 162 cases in which 'frequent return of iritis was observed with rheumatic recrudescences'. In contrast Berens and his associates (1942) did not observe iritis in their series of cases [? number], nor did Rudolph (1945) see it in 150 (presumably adult) men in a military hospital. In 17 out of 28 cases of rheumatic fever Pillat (1935) found small fresh or old choroidal lesions, they were mainly peripheral in position but in two cases looked like milky tubercles. Pillat's findings remain a unique observation. (In 11 of Pillat's 17 cases with positive findings Loewinstein found tubercle bacilli in the blood stream.)

Gout

Whether gout is an affection that has disappeared or one that has been forgotten is a matter of opinion. It is however clear that Sydenham's 'totum corpus est podagra' is hardly applicable to-day, and much that went in the older literature as gouty iritis had as little validity as had the designation of rheumatic iritis. The frequency of iritis in patients known to be suffering from gout does not appear to have been determined. It is of some interest that large series of gout reported in the recent literature make no mention of iritis as one of the complications observed, though others are noted. These reports (by general physicians) cover 116 cases studied by Williamson (1920), 37 cases by Cohen (1936), 93 cases by Hill (1938), 62 by Kinel and Haden (1940), and 100 by Brochner Mortensen (1941). Case reports on the occurrence of iritis in gouty subjects still leave open to question whether there is such a thing as gouty iritis or merely iritis in the gouty. Some hold that gouty iritis is a clear-cut entity characterized by sudden onset, intense conjunctival and episcleral hyperaemia, and but few changes in the iris and little tendency to synechia (Krickmann, 1907, 1910; Wood, 1936). A more convincing feature is the fact that it occurs during an acute attack of gout, and the iritis responds to general treatment such as dietetic balance and colchicum in a parallel manner to the gout (Savin, 1938). The fact that uric acid crystals have been found in the eye in gouty scleritis (Garrod 1866), gouty acute glaucoma (Nivazi and Vefik 1929) and gouty iritis (Wood 1936) is not, as Graham (quoted by Savin, 1938) points out, conclusive evidence of the gouty nature of these particular cases for an inflammation due to any cause would tend to precipitate into the affected tissue the excess of uric acid present in the blood stream. Though final proof is lacking, it would seem that gouty iritis is a clinical entity (Savin).

Discussion

On the basis of the present study and the findings in the literature it may be accepted that iritis is a concomitant lesion in ankylosing spondylitis and in rheumatoid arthritis. In osteoarthritis, gout, and rheumatic fever the position is not clear. That it may be a pointing sign in ankylosing spondylitis is suggested by cases recorded by Wolff (1935), by Krebs (1938) and in the present study.

Ankylosing spondylitis and rheumatoid arthritis are not the only forms of rheumatic disease that have ocular complications nor is iritis the only ocular manifestation of the rheumatic affections. There is a growing and substantial literature on the occurrence of iridocyclitis with a peculiar band-shaped opacity of the cornea in Still's disease (e.g., Holm, 1935, Zeeman, 1940, Blegvad, 1941, Wong 1941, Kurnick, 1942) while scleromalacia perforans (Van der Hoeve 1934, Verhoef and Kins, 1938, Smolero, 1943, Tyrrell, 1945) appears to be associated with rheumatoid arthritis. Moreover, rheumatoid arthritis seems to be part of the Sjögren (1940) syndrome. To stress these clear cut associations is not equivalent to reviving the old conception of 'rheumatic eye disease'. Such emphasis serves two useful purposes.

In the first place, it has a clinical significance in the always difficult task of assessing the causal factor in any particular

case of iritis and iridocyclitis, though obviously the significance of the "rheumatic" factor needs further clarification. Secondly, it has some theoretical value, which extends beyond the question of the rheumatic affections in the narrower sense, for it raises the issue of the association of ocular inflammation with joint inflammation generally. It is recognized that iritis may occur in a whole series of acute infectious diseases with joint manifestations. Apart from gonorrhoeal iritis there are the lesions seen in typhoid, dysentery, "influenza," tuberculosis, and, judging by a recent report (Reed and Goldfain, 1938), also in brucellosis. These lesions, though they may be pyogenic, are not usually so, and their nature is not too clear. Nor is the nature of rheumatoid arthritis and ankylosing spondylitis elucidated, though they are generally regarded as infectious in origin. More consistently than the other arthritides they show no organisms or purulent reactions, and in this they resemble the intraocular inflammations; for iritis, cyclitis, choroiditis, and optic neuritis are not the reactions to organisms in the tissue. The association of iritis with joint affections in general and the rheumatic arthritides in particular raises two issues: (1) Is there a physiological parallelism between the eye and the joint in the reaction to exciting agents?; and (2) What is the nature of the inflammation which produces the non-pyogenic joint reaction and the non-pyogenic intraocular inflammation?

The rheumatologist is perhaps better versed in the problem of the non-pyogenic inflammatory reaction than is the ophthalmologist, but the problem covers common ground for both. Like the oculist, the rheumatologist recognizes inflammation due to the gonococcus, and to a lesser extent the spirochaete; and parallel to the rheumatologist's quest for non-bacterial exciting causes of inflammation is the oculist's recognition of iritis in metabolic disorders (diabetes, and possibly gout), endocrine disturbances (the iridocyclitis of the menopause), neurotrophic disorders (the heterochromia and atrophy of the iris in sympathetic-cord lesions), and chemical factors (the iritis of an ammonia burn of the conjunctiva). It may also be that both the rheumatologist and the oculist deal with fundamentally similar problems because their interest centres in what is possibly a physiologically similar mechanism. The interior of the eye is highly, but not absolutely, protected from abnormalities in the blood stream and from pyogenic invaders by the barrier mechanism in the ciliary body, and it is possible that the blood-aqueous barrier is paralleled by the blood-synovial-fluid barrier located in the synovial membrane. That this is not altogether an idle speculation is suggested by the experimental findings of Angevine and Rothbard (1940). These observers found that, out of 40 rabbits which had received an intravenous injection of relatively avirulent Group A haemolytic streptococci, joint lesions developed in 26 and intraocular lesions in 17 animals. The primary sites of damage were the synovial villi and the iary processes respectively.

Summary

Iritis was observed three times in a series of 123 patients with osteoarthritis, three times in 53 patients with ankylosing spondylitis, and 15 times in 332 patients with rheumatoid arthritis. No cases of iritis were seen in 313 patients suffering from various other forms of rheumatic disease. Assessed against a control series the finding as regards osteoarthritis is not significant, while that relating to rheumatoid arthritis is highly significant.

The iritis observed in the patients suffering from rheumatoid arthritis was mild and unilateral in all but two cases. There was a history of recurrent attacks, always confined to the same eye, in over one-third of these patients. The two patients who suffered from bilateral iridocyclitis were both certifiably blind, one (the youngest patient in the whole series) having no perception of light in either eye.

A review of the literature shows little appreciation of the frequency of iritis in rheumatoid arthritis. In contrast the occurrence of iritis in ankylosing spondylitis is well established. That iritis may be a pointing sign in ankylosing spondylitis is suggested by one case in the present series and two similar observations noted in the literature. Iritis in rheumatic fever appears to be rare; in gout no cases of iritis were observed in the present series, and none were noted in several recent surveys of large numbers of gouty patients, but there seems to be no reason to doubt the validity of gouty iritis as a clinical entity.

Iritis, like rheumatoid arthritis and ankylosing spondylitis, is regarded as an inflammatory reaction. Since neither organisms nor pus are normally recovered from both the inflamed eye and the

rheumatic joint, both these inflammatory reactions have been ascribed to indirect bacterial activity as well as to a whole series of non-bacterial exciting factors. There is undoubtedly some parallelism in the reaction of the eye and the joint to a noxious agent. The problem of intraocular inflammation is similar to that of inflammation of the joint.

We are indebted to Lord Horder and Sir Frank Fox, of the Empire Rheumatism Campaign, for the readiness with which they placed the facilities of their organization at our disposal. Dr. A. C. Elkin, of the West London Hospital; the Physicians to the Red Cross Clinic, Peto Place; Dr. J. Barnes Burt, of the Royal Mineral Water Hospital, Bath; Prof. B. W. Windeyer, of Middlesex Hospital; and the Physicians to the Rheumatic Unit at St. Stephen's Hospital, have all greatly helped by facilities to examine their patients, as have the medical superintendents of the following London County Council hospitals: Hackney; Queen Mary's, Carshalton; Lambeth; South-Western; St. Alfege's; St. Benedict's; St. Luke's; St. Pancras; St. Francis; and St. John's; as also Dr. J. N. Deacon, of Redhill Hospital, Edgeware. We are particularly obliged to Dr. Francis Bach, Dr. J. L. Hamilton-Paterson, and Dr. Kenneth Stone for the trouble they have taken and for much helpful advice. We are also indebted to Dr. J. A. Fraser Roberts for assessing our findings statistically.

The Medical Research Council has issued as No. 253 of its Special Report Series a survey by Dr. B. S. Platt entitled *Tables of Representative Values of Foods Commonly Used in Tropical Countries* (H.M. Stationery Office; 9d.). The compilation of a table of food values for use in Nyasaland and areas consuming similar foods was the foundation from which the present tables have been built up. They are the first published results of the Nyasaland survey undertaken to determine the relation of economic, sociological, and agricultural matters to nutrition, as well as the correlation of health with the nutritive value of the diet.

PREVENTION OF TRANSFUSION REACTIONS DUE TO Rh FACTORS

BY

F. W. GUNZ, M.D., M.R.C.P.

Assistant Clinical Pathologist, Addenbrooke's Hospital, Cambridge

During the past few years there have been many reports of intra-group haemolytic blood transfusion reactions caused by Rh antibodies (Levine and Stetson, 1939, Wiener and Peters, 1940, Boorman *et al.*, 1942, Diamond, 1942, Wiener *et al.*, 1942, Dameshek and Levine, 1943, Mollison 1943, Beck *et al.* 1944, Callender and Paykoc, 1946, Callender *et al.* 1945, Diamond, 1945, Drummond *et al.* 1945, Plaut *et al.* 1945). The importance of routine determination of the Rh type of patients requiring transfusion has been widely stressed. The Rh antibodies differ from the inter group agglutinins of the ABO system in that, with very rare exceptions (Diamond, 1942), they do not occur naturally, but are formed by the Rh-negative subject in response to sensitization, either from an Rh positive foetus *in utero* or from a transfusion of Rh positive blood. Hence it is most unusual for first children to show signs of haemolytic disease or for Rh negative patients to suffer haemolytic reactions during a first blood transfusion although antibodies may be formed rapidly enough to curtail the useful life of Rh positive cells given in a first transfusion.

It is fortunate that sensitization to the Rh factors occurs only in a minority of subjects at risk. The chance of an Rh-negative woman forming antibodies against the blood of her Rh positive foetus has been variously estimated as between 1/20 and 1/40 (Haldane 1942), but these figures are based on data for the incidence of neonatal haemolytic disease obtained before the discovery of the Rh factors (Darrow, 1938). In the case of Rh negative recipients of Rh positive blood transfusions, little is known beyond the fact that sensitization is by no means invariable. Callender and Paykoc (1946) found anti-Rh agglutinins in 1 of 17, and Moloney (1945) in 1 of 18 Rh negative patients who had received multiple blood transfusions. Callender and Paykoc's patient was a woman, but as she had not been pregnant the antibody must presumably have been formed in response to transfusions of Rh-positive blood.

No doubt can exist that in an ideal transfusion service the Rh type of every recipient should be determined before transfusion, and that only blood of the appropriate type should be given. The difficulties in establishing such a service are, however formidable. Special grouping laboratories have been set up for this purpose in several American cities (Barton, 1944, Butler *et al.* 1944, Diamond, 1945, Young and Karlier, 1945), but the procedure is so cumbersome and expensive that it has so far been found necessary to restrict Rh typing to special groups of recipients. Diamond's laboratory performs 300 Rh tests and 50 anti-Rh determinations each week, it is obvious that special laboratories of this kind are warranted only in large centres where they can serve a whole group of hospitals. Furthermore, so long as the approximate percentage of patients susceptible to sensitization remains unknown the justification for such an elaborate system is doubtful.

Aim and Method of Present Investigation

The present investigation was undertaken with the following aims: (1) to discover if a blood transfusion service could be run in a medium-sized hospital with an average clinical laboratory, so as to eliminate the likelihood of haemolytic transfusion reactions due to Rh antibodies, (2) to determine the rate of formation of Rh antibodies in an unselected series of patients receiving multiple blood transfusions. For this purpose it was decided to confine Rh typing to two categories of patients: (a) those who had received a previous transfusion of Rh positive or unknown blood, (b) those with an obstetric history suggestive of a possible sensitization to the Rh factors.

The accompanying special application form (see Fig.) was distributed to all wards and departments and blood was issued only after receipt of the completed form accompanied by citrated and clotted samples of the patient's capillary blood.

The ABO group was determined in all patients. In the case of patients falling into Category *a* or *b* the Rh type was determined by means of an anti Rh, (anti D) serum, and blood of the appropriate type was issued. In all other instances Rh positive blood was issued, except in a small number at times when Rh negative blood happened to be in greater supply than Rh positive. The homologous group was given to Group A and Group O recipients, and Group O blood to Group B and Group AB recipients. Rh negative blood was usually available at the local blood bank, and a special effort was made always to have in the hospital store at least one bottle of Rh negative blood of Groups A and O. In only one or two cases were Rh-negative donors specially bled.

ADDENBROOKE'S HOSPITAL, CAMBRIDGE

APPLICATION FOR BLOOD FOR TRANSFUSION

This form, completed by the Sister or the Nurse-in-Charge, and accompanied by samples of the patient's blood taken from the ear lobe or finger, must be sent to the Clinical Laboratory before any blood transfusion is given.

Patient's Name	Sex	Age	Ward
Name of H.P. or F.S.			
Disease			
(1) Has patient ever had a previous blood transfusion? (If so give details)			
(2) Has patient had a baby (or babies) suffering from oedema (it does not mean severe jaundice, or profound anaemia)?			
(3) Has patient had repeated miscarriages or stillbirths?			
If answer to any of the three questions is "Yes" on a P. card must be given unless the clinical pathologist has been personally consulted. After every blood transfusion on the bottle(s) should be returned to the Clinical Laboratory.			
Date	Signature		
NOTES FOR LABORATORY USE			

When a patient in Category *a* or *b* was found to be Rh-negative a sample of venous blood was obtained and the serum examined for evidence of anti Rh agglutinins. The incomplete antibody (Race, 1944, Wiener, 1944) was not sought for. It must be stressed that antibodies were looked for before a repeat transfusion, and not after a potentially sensitizing transfusion. It was thought that this would give a more useful answer to an inquiry concerned with conditions obtaining in routine transfusion practice.

After each transfusion a careful inquiry was made into the possible occurrence of reactions. When any reaction was reported, such as rise of temperature, rigor, discomfort, or pruritus, another specimen of venous blood was obtained, and the cause of the reaction investigated with the help of the pre- and post-transfusion samples of the recipient's blood, and the blood remaining in the transfusion bottles.

Every care was taken to make the series representative of the entire transfusion work of the hospital. The only patients excluded were infants suffering from definite haemolytic disease.

Results

This report covers a period of 17 months in a hospital of 800 beds. During this time 232 patients (110 male, 122 female) were given a total of 292 transfusions for which 620 standard bottles of blood were used. The total number of transfusions given in the hospital was somewhat larger, the probable difference amounting to about -10%. Multiple transfusions given to any individual patient within a period of seven days are classified as a single continuous transfusion, as it is unlikely that antibodies developed immediately after the first transfusion.

During the 17 months 58 patients (34 male, 24 female) received either more than one transfusion or second transfusions after a potentially sensitizing transfusion given before the start of this inquiry. Of these, 48 (83%) patients (27 male, 21 female) were Rh positive and 10 (17%) patients (7 male, 3 female) were Rh-negative. The figures closely approximate those found in the general population, and tend to show that the sample was a representative one. Among the Rh-negative

patients, two (1 man, 1 woman) developed antibodies; six did not develop antibodies; and two were not tested.

Case 1.—Mrs. A., aged 33. Tuberculous peritonitis. Two normal pregnancies four and eight years previously. No stillbirths or miscarriages. May 15, 1944: Given a transfusion of unknown blood. No reaction. Sept. 7: Application for blood for further transfusion. Found to be Group A Rh-negative. Anti-Rh agglutinin present at titre 1:4. Given two bottles of Rh-negative blood. Further transfusions of Rh-negative blood on Oct. 4 and Dec. 12. No reactions to any of these.

Case 2.—Mr. B., aged 23. Infected compound fracture of femur. Jan. 4, 1944: Given two bottles of unknown blood. No reaction. Jan. 13: Given two bottles of unknown blood. No reaction. June 21: Application for blood for further transfusion. Found to be Group O Rh-negative. Anti-Rh agglutinins present. Given one bottle of Rh-negative blood without reaction.

The Rh type was also determined in three women in Category b (obstetric cases) who were about to have first blood transfusions. One was Rh-positive and two were Rh-negative. No antibodies were present in any of their sera, and no reactions followed the giving of appropriate blood.

Reactions

A total of 17 (5.8%) reactions occurred among the 292 transfusions. These are classified in the following table. It was

The Reactions Classified

Slight or moderate rise of temperature (1-3° F.: 0.5-1.6° C.)	6
Mild or moderate rigor	7
Jaundice	2
Urticarial rash	2
Total	17

noticeable that, although special inquiry was made in each case, no reaction was said to be accompanied by backache. No patient was upset by the reaction for more than an hour at most; and several reactions produced no subjective symptoms. In no case was incompatibility of the blood or the presence of irregular antibodies found on subsequent investigation. The reactions were ascribed to various causes such as pyrogens, a too rapid rate of transfusion, or allergy.

Discussion

No claim can be made that sensitization of two Rh-negative patients among 10 who had received Rh-positive or unknown blood represents the true rate which might be found in the general population; for this was only a small sample, although it was unselected. Furthermore, the incomplete antibody, now known to occur fairly frequently, was not tested for; had this been done the percentage of sensitized patients might have been higher. It is of interest that strong antibodies were circulating in the blood of the patients as long as four and five months respectively after their sensitizing transfusions. The inference may be drawn that both patients would have suffered haemolytic reactions had they been given Rh-positive blood for their subsequent transfusions.

Although it is true that the sensitization rate of 2 in 10 Rh-negative patients is probably not an accurate guide, it might serve as a rough indication of the actual problem facing an average hospital transfusion service. On the basis of a 15% incidence of Rh-negative subjects in the general population, it can be assumed that there were 35 Rh-negative patients among the total of 232 transfused. Of these, 7 would have been sensitized if the rate of 2 in 10 observed in this inquiry were generally applicable.

In an ideal transfusion service it is clearly desirable to prevent the occurrence of any sensitization. In particular, women in the child-bearing period may be sensitized, and so produce in subsequent pregnancies children suffering from haemolytic disease. This is certainly a grave risk, although it can affect only a small number of women, and several undoubted instances have been recorded. There is, however, only one possible way of attaining complete prevention—namely, to determine the Rh type of every recipient before transfusion and to administer blood of the correct type. At present, in the great majority of hospitals, sufficient laboratory facilities do not exist to allow universal Rh typing at a moment's notice; nor is there an unlimited supply of Rh-negative blood.

If, therefore, it be admitted that transfusion sensitization cannot at present be avoided in all cases, it is essential at least to attempt to prevent reactions due to sensitization. This inquiry has shown that the rate of occurrence of haemolytic reactions can be decreased by adopting the procedure outlined. In a total of 292 transfusions no reaction was attributable to sensitization by Rh antibodies; although there were at least two patients who had in fact been sensitized and would probably have suffered haemolytic reactions in the absence of precautions.

If all Rh-negative patients in this series had received the correct type of blood for each transfusion, it is estimated that 92 standard bottles of Rh-negative blood would have been needed. By following the procedure described above, however, only 30 bottles were actually used, which shows that tenuous stocks of Rh-negative blood can be employed economically, and that a comparatively small panel of known Rh-negative donors can supply the needs of a moderately large hospital.

Summary

During a period of 17 months, in a hospital of 800 beds, a scheme has been operating designed to prevent haemolytic transfusion reactions due to Rh antibodies.

232 patients received 292 transfusions; of these, 58 had more than one transfusion.

No haemolytic reactions occurred during the period of the investigation.

Of 10 Rh-negative patients who received multiple transfusions two were found to have developed Rh antibodies.

My very warm thanks are due to the Galton Serum Unit, Cambridge, and in particular to Dr. R. R. Race, for constant help and advice during the course of this investigation.

The annual general meeting of the Central Council for District Nursing in London was held at the County Hall. The Council now comprises 84 district nursing associations in the metropolitan area, among which grants to the amount of £23,894 were distributed during 1945. These included a public assistance subsidy of £12,000 from the London County Council, and a further sum from the Council of £7,446 on account of the new 50% Government grant for the salaries of nurses. London Parochial Charities contributed £3,842. It was stated that the King Edward's Hospital Fund for London is to entrust the Central Council with the distribution of its annual grant of £2,500, with an addition of £250 for administrative expenses. This grant was originally designed to help to relieve the pressure on the out-patient departments of hospitals. Under the Act of 1907, which incorporated the fund, the interpretation clause cites "nursing institutions" as available for support from the capital income. The L.C.C. public assistance patients visited by district nurses for the purpose of general nursing during the year numbered 6,197, and 152,696 visits were paid; in addition 98,029 visits were paid to 1,442 cases for the administration of insulin. It was mentioned in the report that after July 1 of the present year training in the administration of gas-and-air analgesia will form part of the midwife's course, and proficiency therein will be a necessary part of her final qualification. It is believed that with the help of the College of Midwives some arrangement may be made for early training of midwives in the use of this analgesia, for which there is said to be an increased demand in London. Another point brought out in the report is the great influence of the district nurse in encouraging recruits to the nursing profession. Her special type of work makes a great appeal to young women. Sir Harold Kenyon is the new chairman of the Central Council, in succession to Sir William J. Collins.

SPONTANEOUS HYPOGLYCAEMIA ASSOCIATED WITH EPILEPSY; SUBTOTAL PANCREATECTOMY

BY

N. G. HULBERT, M.D., M.R.C.P.

Temporary Assistant Physician

AND

R. J. McNEILL LOVE, M.S., F.R.C.S.

Honorary Associate Surgeon

West End Hospital for Nervous Diseases

Reports of cases of spontaneous hypoglycaemia treated by partial pancreatectomy are uncommon in this country, although American literature contains numerous accounts of the surgical treatment of pancreatic hyperactivity. The case herewith reported is of interest in that the symptoms of hypoglycaemia were associated with epilepsy, which confused the clinical picture in the earlier stages of the illness. Although, most unfortunately, the patient succumbed from pulmonary infarction, he lived long enough to demonstrate the remarkable improvement which followed subtotal pancreatectomy.

Case History

In 1922 the patient, then aged 41, had his first fit. He had just begun his morning's work when without warning he fell on his face unconscious. He understood that he lay quite still, was uncertain if he bit his tongue, but remembered having "wetted his trousers." He was taken home unconscious. His doctor said that his heart was in a bad state and that he smoked excessively. During the same day he had three further fits, with twitching movements all over the body, and believed that he remained unconscious for some seven hours in all.

A doctor again examined him that evening and the following day. He then referred him to one of the larger London teaching hospitals. Here his skull was x-rayed in three positions and a blood test taken. Bromide and luminal (phenobarbitone) were prescribed. Following this the fits recurred, but gradually they became less frequent. After some five years of treatment he enjoyed an interval of about two years with freedom from fits, and so gave up attending the hospital for three months. Cessation of treatment was, however, followed by a recurrence of the fits, and so he resumed his attendance at the hospital and continued the treatment until the outbreak of war, when he was transferred to the Metropolitan Hospital with a diagnosis of epilepsy.

On Oct. 19, 1939, he first attended the general medical out-patients department of the Metropolitan Hospital. He was seen by the house-physician, who considered the symptoms to be compatible with the diagnosis of idiopathic epilepsy. The patient was therefore treated with phenobarbitone, gr. 1 (65 mg.) b.d. On April 19, 1941, he stated that he felt well and was working, and had remained free from fits for two years while taking the tablets.

On Jan. 24, 1942, he first reported the occurrence of peculiar attacks unlike his fits. He had had six of these attacks in the previous two weeks, four occurring on the same day. In the attacks he saw "something terrible coming towards him"—so terrible that he was unable to describe it. He felt, however, that it concerned the Germans, and explained that he had been a prisoner of war for nine months in the 1914-18 conflict, which had greatly upset him, as, though he had often thought that he might be killed, he had never contemplated being a prisoner. After this feeling of "terrible fear" he experienced a peculiar sensation in the stomach, but found that if he gripped the bench hard this might pass off, leaving him very weak; otherwise he would collapse suddenly without further warning. After these attacks, for 24 hours he felt choking in the throat, was unable to speak easily, and wished to cry. He then stated that these "attacks" had been occurring for the past eighteen years as well as the fits, which he had previously described. At first they had occurred at intervals of two or three months, but in the last six months more frequently, and he noted that he tended to have several attacks one month and then a period of freedom. These attacks would occur at any time of day, but were more frequent before midday. He himself had noticed no relation between the attacks and the times of his meals or of his work. His work involved heavy manual labour, and his wife had often said that he should not go to work without more food. He continued on phenobarbitone, but on July 11, 1942, reported seven of these attacks occurring on one day, and was therefore referred by the house-physician for a further opinion.

On July 15 he was first seen by one of us (N. G. H.), and a tentative diagnosis of hypoglycaemic attacks was considered. Admission

was arranged to the West End Hospital for Nervous Diseases for further investigation.

Habits.—The patient was a french-polisher. He drank on the average one pint (568 ml.) of beer and smoked 1/2 oz. (14 g.) of tobacco daily. His usual meals were as follows: 6.30 a.m.: A cup of tea and one piece of bread-and-jam. 9.30 a.m.: Breakfast at work—a cup of tea, and a sandwich of bread and bacon. 1 p.m.: A meat or fish dish with bread, followed by pudding or a sweet. 3.30 p.m.: A cup of tea and a piece of cake. 6 p.m.: 1 pint of ale. 7 p.m.: His main meal—e.g., a chop and vegetable, followed by a sweet or pudding.

Condition on Examination.—He was admitted to the West End Hospital on Aug. 10, 1942. Weight 8 st. 11 lb. (55.7 kg.). He previously highest known weight having been 9 st. 4 lb. (59 kg.). He was well developed and his general nutrition good. He appeared younger than his age. Full neurological examination proved normal. With the exception of some slight emphysema and a few rheas in the chest, a comprehensive examination also proved normal. The B.P. was 140/90 and the pulse rate 65-80 and regular. On examination the urine was normal.

Investigations.—The C.S.F. showed a pressure of 140 mm., no cells, a slightly raised protein of 70 mg. per 100 ml., no excess of globulin, and a normal colloidal gold curve. The Wassermann and Meinicke flocculation tests in both blood and fluid were negative. Skiagrams of the skull and pituitary fossa were normal. Skiagrams of the suprarenal region showed no abnormality.

Blood-sugar examinations on Aug. 12 (patient on normal full diet previously) gave the following results. Glucose-tolerance curve:—Fasting, 53 mg. per 100 ml. After 30 g. of glucose: 1/2 hour, 109 mg.; 1 hour, 133 mg.; 1 1/2 hours, 32 mg.; 2 hours, 32 mg. per 100 ml. (Urine specimens fasting and at 1 and 2 hours contained no sugar.)

Aug. 18.—The patient was ordered a diet containing 400 g. carbohydrate a day. Food was taken every two hours by day, and, if waking, in the night.

Aug. 19.—Glucose-tolerance curve:—Fasting, 52 mg. per 100 ml. After 50 g. glucose: 1/2 hour, 80 mg.; 1 1/2 hours, 65 mg.; 2 hours, 72 mg. per 100 ml.

Aug. 31.—Blood sugar on waking in morning, 39 mg.; 2 hours after midday meal, 75 mg. per 100 ml.

Sept. 7.—At 6.30 a.m. the patient had a full breakfast of cereal, milk, and sugar, 2 slices of bread-and-butter and jam, and tea. At 9.15 a.m. he developed an attack, and the blood sugar was found to be 56 mg. per 100 ml. Glucose (50 g.) was then given, and half an hour later the blood sugar was 72 mg. per 100 ml.

A blood count on Aug. 24 showed: Hb, 102%; red cells, 5,760,000; C.I., 0.97; white cells, 7,200. Blood sedimentation rate (Westroble, 100 mm. col.), 2 mm. in 1 hour. An electro-encephalogram taken on Sept. 1 (by courtesy of Dr. Dennis Hill) showed the following results: Dominant rhythm, 10 per second—voltage 50 microvolts; regularity good; no abnormal rhythms; stable on hyperventilation. Conclusion: within normal limits.

While the patient was in hospital a number of severe hypoglycaemic attacks were observed, which were not relieved by a diet of 4,000 calories over a period of five weeks. In view of this and of the results of the clinical investigations, and also of the progressive nature of the illness, it was decided to explore the pancreas for an islet adenoma, and, if such were not found, to perform a subtotal pancreatectomy.

Operation (McN. L.).—On the morning of the operation the blood sugar was 66 mg. per 100 ml. The patient's blood was Group A. An upper transverse abdominal incision was made an inch below the ninth costal margin. The rectus muscles were divided by diathermy and the abdomen was opened. The stomach was displaced upwards, and the lesser sac was opened by an incision through the gastro-colic omentum, and the mesocolon was divided. By this means efficient exposure of the pancreas was obtained. A careful search failed to reveal an adenoma, so it was decided that a subtotal pancreatectomy should be performed. A splenectomy was carried out in order to obviate troublesome haemorrhage from the splenic vein, which is normally partially embedded in the pancreas. The tail and body of the pancreas were then mobilized, and about three-quarters of the gland removed with a diathermy knife and immediately fixed for histological examination. The raw surface was oversewn with mattress sutures. After insertion of a rubber drain the abdominal wall was closed in layers. After the operation the patient was somewhat shocked, but recovered from the anaesthetic. His condition steadily improved until the following day, when he suddenly collapsed and died, twenty-five hours after the operation. The blood sugar the morning after the operation rose to 130-140 mg. per 100 ml. (The details of this reading were destroyed by enemy action.)

Necropsy (Dr. Carnegie Dickson).—The abdominal wound was reopened and the intestines found to be distended with flatus. There

was only a slight accumulation of blood-stained fluid in the flanks and in the bed of the spleen. No evidence of fat necrosis was seen. Careful investigation of the mesentery of the bowel, retroperitoneal tissues, and elsewhere showed no accessory pancreas in which an adenoma might have developed. No adenoma was found in the remaining part of the pancreas. The liver was normal apart from moderate fatty degeneration and some venous congestion. Both kidneys showed some cloudy swelling; otherwise there was nothing of note. Both suprarenals were normal. The lungs showed a very patchy congestion, some of which was due to areas of multiple infarction. There was no acute pneumonic consolidation. The pituitary gland and thyroid both appeared normal. The heart and aorta were normal. *The Brain:* The leptomeninges showed a very distinct degree of fibrous thickening over the hemispheres, especially over the vertex, where the convolutions were distinctly narrowed and atrophied. Exaggeration of the sulci in the region of the thickened leptomeninges was as pronounced as in many cases of advanced general paresis.

Histology.—An extensive series of sections of the pancreas stained for islet tissue showed nothing suggestive of hyperplasia or tumour. Complete histological examination of the other organs, including the brain, was not possible owing to the destruction of the specimens by enemy action.

Discussion

The normality of the pancreas in this case is noteworthy. The very full pathological examination, including the search for accessory pancreatic tissue, excluded the possibility of an islet adenoma having been missed at operation.

A lesion of the hypothalamus in the region of the paraventricular nuclei might explain the picture, as Barris and Ingram (1936) have shown in cats that this may cause permanent hypoglycaemia and increased sensitivity to insulin. A similar mechanism is possibly the basis of obesity and hypoglycaemia following some cases of encephalitis.

Hypoglycaemia itself may also produce lesions in the brain consisting of widespread degeneration and necrosis of the nerve cells with corresponding glial proliferation. It has been thought that this is due to the failure of the vital oxidative processes from lack of glucose, probably reinforced by vasomotor disturbances. In the 6 cases described by Lawrence, Meyer, and Nevin (1942) this mainly affected the cerebral cortex, caudate nucleus, and putamen, and to a less extent the cerebellum. It is therefore unfortunate that it was not possible to examine the brain in detail.

The epilepsy of late onset was possibly associated with the hypoglycaemia, as a low blood sugar may induce fits in a patient not normally epileptic, while resistant cases of epilepsy are sometimes found to have low blood-sugar levels.

Whatever the aetiology of this case, however, the severity of the attacks and their failure to respond to dietetic treatment (Whipple and Frantz, 1935) would almost certainly have caused a fatal coma, and so operation was fully justified.

We would like to thank Dr. Worster-Drought for his advice and Dr. Carnegie Dickson, Mr. Martin, and Miss Wilson for the pathological investigations; and Dr. Dennis Hill for the electroencephalogram.

While a number of Citizens' Advice Bureaux and voluntary organizations in London have had cause to be grateful for the information circulars issued by the London Council of Social Service, there must be a large public which is unaware of them and will be glad to know that they are to be more widely available. The circulars are published at three-weekly intervals, and their aim is to keep the reader informed of social needs and developments—that is, to pass on the varied knowledge the council acquires through its research and information department. They contain, for example, summaries of new regulations and Acts of Parliament, notes on new and existing social services, and comments on new trends in public opinion and social policy. They will be of value, therefore, not only to social workers, but to M.P.s, local government officers, and staff managers generally. The annual subscription is £1 1s, and membership forms can be obtained from the London Council of Social Service, 7, Buxley Street, London, W.C.1.

OCCURRENCE OF OVULATION AND CAUSES OF STERILITY IN METROPATHIA HAEMORRHAGICA

BY

IVAN B. GARTSIDE, M.A., M.R.C.S., L.R.C.P.

(From the Pathology Department, St. Luke's Hospital, Bradford)

This note records evidence of ovulation in a typical case of metropathia haemorrhagica and suggests that the sterility associated with this condition can be due to causes other than an anovulatory cycle.

Case Report

The patient, aged 40, has five children, the youngest 11 years old. She was admitted for menorrhagia and metrorrhagia of three years' duration, a temporary remission of symptoms having followed curettage two years ago. Since the onset of irregular periods her cycle has been 7 to 8 days' bleeding, usually excessive, the intervals varying from 28 to 35 days, while periods of bleeding up to six weeks' duration have occurred latterly. Subtotal hysterectomy revealed a cystic right ovary about 3 cm. in diameter, the left ovary being normal.

Pathological Findings.—Macroscopic section showed moderate symmetrical enlargement of the uterus due to myohyperplasia, with a thickened haemorrhagic endometrium about 6 mm. in thickness in the fresh specimen. Two small intramural fibroids were also present. Rather more than half-way down the posterior wall a small endometrial polyp-like structure projected about 4 mm. into the uterine cavity, and a portion of endometrium and myometrium including this small mass was sectioned. The gross morbid anatomical characteristics were thus consistent with the clinical diagnosis of metropathia haemorrhagica.

Histology.—The curettage made two years ago followed a fortnight of continuous bleeding and the scrapings were post-menstrual, showing no progesterone activity. In the present specimen (see Fig.)

Photomicrograph showing mass of degenerate chorionic villi and adjacent oestrogenic endometrium. Stained Heidenhain's iron haematoxylin.

the myometrium showed no abnormality, apart from the fibromyoma, while the endometrium presented an extremely interesting picture. It was of "mixed" type, a very few glands showing early secretory activity, while the majority were in the oestrogen phase, some with cystic dilatation. In glands where secretory activity is evident this is often limited to a few cells, the remainder presenting an even and regular luminal border. What appeared macroscopically to be an endometrial polyp proved to be a mass of degenerate chorionic villi, lying mostly outside the endometrium and projecting into the uterine cavity. The penetration of trophoblast into the endometrium was limited to a depth of approximately 0.5 to 1 mm. Decidual reaction was pronounced in the stroma, and the hypertrophied decidual cells showed the intermingling with numerous lymphocytes which is characteristic of early pregnancy. In general, the stromal picture was in marked contrast to the glandular picture.

Discussion

The endometrial glands in the above case present evidence of a prolonged oestrogen phase, although the partial onset of

secretory activity shows the influence of progesterone at this time. The mass of chorionic villi is proof of ovulation, though in the preliminary trimming of the block the ovum was lost.

Those cases of irregular and excessive uterine bleeding in which no local abnormality is detected are now regarded as determined by ovarian dysfunction, and are placed together under the term "metropathia." The histological picture in the endometrial glands of a large group of such cases is one of prolonged oestrogen activity and has been interpreted as evidence either of an excessive oestrogen phase or of an anovulatory cycle. In cases where examination of the pelvic organs has been made a cystic ovary has usually been found, and the underlying pathology has been considered to represent the repeated onset of a cystic degenerative process in the ripening follicle, before ovulation. Increasing attention has been paid to ovarian dysfunction of this type as a cause of sterility (Mazer and Zisermann, 1932; Mazer, Israel, and Kacher, 1937; Jeffcoate, 1935; Mason, Black, and Gustavson, 1938).

The present case shows that ovulation may occur in clinically and pathologically typical metropathia haemorrhagica, while the histology demonstrates a second possible cause for sterility in this condition. It shows that in addition to infrequency or total absence of ovulation, with its relative or absolute reduction in the chances of fertilization, nidation may be incomplete, and this inability of the fertilized ovum to embed itself may be due to the partially or completely unprepared state of the endometrium. In the later phases of a normal cycle pregestational changes take place both in the glands and in the stroma of the endometrium; but in this case stromal change was fairly well developed while glandular response was scarcely apparent. The importance of adequate concentrations of corpus luteum hormone for implantation of the ovum has been emphasized by several authors. Browne *et al.* (1939) state: "A short corpus luteum phase has been observed in some patients with sterility in whom no other cause for infertility has been detected." Allen and Corner (1929) first demonstrated the necessity for progesterone in the implantation of early embryos, and their observations have often been confirmed. The present specimen shows that in habitual abortion where the probable cause is inadequate progesterone production the administration of that hormone during the latter half of the cycle is probably soundly based on the pathogenesis of the condition. Progesterone is commonly stated to produce the pregestational changes in the endometrium, and these changes affect both the uterine glands and the stroma. The stromal reaction is marked in this case, but the glandular one lags far behind. In his monograph Hamblen (1939) calls attention to the evidence that "mixed" endometria probably represent partial inability of the endometrium to respond to the pregestational principle, but evidence is presented here that the response of the endometrium to progesterone can be unequally distributed as between the glandular elements and the stroma, as otherwise the two reactions must be assumed to be separately conditioned, and of this there is as yet no evidence.

Summary

A case is described of metropathia haemorrhagica in which the presence of chorionic villi shows that ovulation had occurred.

The suggestion is made that sterility in this condition may be due not to the absence of ovulation but to inability of the fertilized ovum to embed itself in an endometrium wholly or partially unprepared for its reception.

I am most grateful to Mr. H. A. Hamilton for allowing me to use his clinical findings, and to the medical superintendent, Farnborough County Hospital, for permission to publish this case.

Before the war Mrs. R. G. Edwards raised a fund to provide the best means of combating primary tuberculosis in children by early treatment. It has been decided to devote this fund to the construction at Papworth of a home to be known as the Edith Edwards Children's Home.

TREATMENT OF SULPHONAMIDE-RESISTANT GONORRHOEA BY PENICILLIN

BY

ROBERT LEES, M.D., F.R.C.P.Ed.

This communication is based on observation of a large series of cases treated in the C.M.F. and a smaller number treated in the U.K. It has already been recorded by Campbell (1944) and Bell (1945) that a high proportion of cases of gonorrhoea in our Forces in Sicily and Italy proved resistant to routine methods of treatment with sulphonamides. On further investigation it was found that a considerable proportion of gonorrhoea cases were rendered "sulphonamide-resistant" by use of a dosage scheme which employed 4 or 5 g. of sulphapyridine or sulphathiazole a day for two days. Other cases were rendered sulphonamide-resistant by self-treatment, or by irregular dosage, or by taking a small number of tablets to obscure the diagnosis and thus evade the penalties of venereal infection. Prolonged treatment with high dosage of sulphathiazole or sulphadiazine (6 to 8 g. daily for 10 days), even when reinforced with non-specific "shock" and fever therapy with intravenous injections of typhoid vaccine, failed to produce more than 70% of cures. This must be ascribed to a high proportion of sulphonamide-resistant strains of gonococcus in the population, but no evidence could be found to support the popular theory that the Italian prostitutes were habitually taking small doses of sulphonamides which, although insufficient to cure gonorrhoea, were enough to minimize the signs and symptoms of the disease.

The high incidence of V.D. in the Allied Forces in C.M.F. with the low percentage of cure in gonorrhoea led to the accumulation in hospital of very large numbers of chronic and resistant cases of gonorrhoea, and on arrival in Italy in March, 1944, I found there were over 2,000 such cases. Hospital accommodation was overtaxed; the men were urgently needed for the battles of Cassino and Anzio; accommodation had to be provided for battle casualties.

A series of 1,737 cases of sulphonamide-resistant and chronic and complicated cases of gonorrhoea were treated with penicillin. Many had been treated for weeks or even months without cure, and several had genito-urinary complications of gonorrhoea such as prostatic-vesiculitis and epididymitis. No case of metastatic complication of gonorrhoea was included in this series. The worst cases were chosen. The treatment was done with such amounts of penicillin as were available after the needs of war wounds and urgent medical and surgical cases had been met. The diversity of the dosage scheme is to be explained by the shortage of penicillin and the desire to obtain the maximum number of cures with the minimum consumption of the drug. Supplies were available irregularly at that time. It was also urgently necessary to return key-men to full duties as quickly as possible. These factors governed and modified this therapeutic experiment.

Dosage.—Penicillin was given in every case as 10,000 units dissolved in sterile distilled water or saline and injected intramuscularly at intervals of three hours. No pain or abscess formation resulted from the injections.

Results

The results are analysed according to dosage:

Dose	No. of Cases	% Cured
100,000 units	344	92.0
60,000 "	1,333	94.3
50,000 "	100	92.0
30,000 "	50	80.0
Total treated by various doses	1,737	93.9

Results of re-treatment with penicillin of the cases (6.1%) noted above as failures are available in 73 cases, and all but one were cured. Such cases were re-treated as soon as possible by penicillin in the same individual dose (10,000 units at three-

hour intervals), but the duration of treatment was prolonged until a larger total had been given, as follows:

120,000 units	14 cases
150,000	"	23 "
200,000	"	34 "
240,000	"	2 "

Subsequent experience with subjects not in this series has shown that all cases of gonorrhoea are not cured by re-treatment even with 240,000 units given as 15,000 units or 20,000 units at intervals of three hours. In all such resistant cases it was our custom to cultivate the organism, identify it, and test its resistance to penicillin *in vitro*. In no case was a penicillin-resistant strain of gonococcus found. Such cases are probably explained by persistence of gonococci in a closed focus of infection such as a prostatic abscess or a sealed-off infection of a seminal vesicle.

Notes on a number of patients treated with 50,000 units indicate that this amount is below the optimum dosage. For example, Case 207 relapsed with acute epididymitis twelve days after penicillin treatment, and Case 200 had gonococci in the para-urethral ducts on completion of the five injections of penicillin. Cases 295, 296, 298, and 299 showed gonococci on the third, fourth, ninth, and fifth day, respectively, after penicillin treatment. These cases were all cured ultimately with local treatment and sulphonamides.

Disappearance of sulphonamide resistance seemed to occur in several instances after unsuccessful penicillin treatment. Several patients who had been treated (perhaps badly) with sulphonamides and had acquired a chronic "sulphonamide-resistant" state were not cured by penicillin in the doses employed. But subsequent re-treatment with sulphathiazole produced a rapid and permanent cure. This procedure is not advised in preference to re-treatment with larger doses of penicillin, and success was by no means invariable.

Synergic Effect of Penicillin and Sulphonamides.—A small series of cases were treated with sulphathiazole, 5 g. a day, and 30,000 units of penicillin on the fifth day. The results were not good, and we could not confirm the published reports that there was a marked synergic effect and that 100% cures could thus be achieved quickly. It was considered that such schemes of treatment were unlikely to have much future value, and the experiment was not pursued.

Speed of Action.—The speed of action of penicillin is of some importance in deciding the precautions necessary, such as isolation of patients and sterilization of fomites. In this series it was the practice to take a urethral smear before the fourth injection was given—that is, after the patient had received 30,000 units and nine hours had elapsed since penicillin treatment began. This was also done after 60,000 units and after 100,000 units had been given. Typical results are those recorded (by Major Priest) in one series of 186 cases: after 0,000 units, 16 gonococcus-positive; after 100,000 units, 3 gonococcus-positive. Two of these cases showed gonococci in slides for 12 to 24 hours after treatment, but the organism disappeared without further treatment. The gonococci were swollen and atypical in appearance and did not grow in cultures.

Effect of Higher Dosages of Penicillin.—A smaller series were treated at a later date with 20,000 units of penicillin every three hours until 100,000 units were given. In a series of 204 cases cure was achieved in 97%. This scheme of five doses is much more convenient than ten doses, for treatment can be completed within twelve hours. Ambulatory patients spent one night in hospital and returned to work next morning, injections being given at 5 p.m., 8 p.m., 11 p.m., 2 a.m., and 5 a.m.

The results of treatment with four doses, at four-hour intervals, of 25,000 units were less satisfactory. In a series of 200 cases the rate of cure was 92%.

Gonococcal Ophthalmia.—One case of ophthalmia was observed in which the patient had infected his eye, and as the organ was completely sulphonamide-resistant it was feared that the eye infection might be intractable. Treatment was given by 100,000 units of penicillin, administered as ten doses of 10,000 units at three-hour intervals. In addition drops of penicillin solution in a strength of 1,000 units per ml. were instilled into the conjunctiva after preliminary washing with

sterile normal saline. The patient made a very rapid and complete recovery.

Gonococcal Prostatitis and Epididymitis.—Many cases of subacute prostatitis and of acute epididymitis were treated according to the dosage scheme of 100,000 units in ten injections. The results were very satisfactory; resolution of the inflamed organ took place rapidly, and was usually complete within ten days without additional treatment.

Observation and Test of Cure.—Cases were followed for three months. Urethral and prostatic smears were taken frequently during the first two weeks, but thereafter observation was, of necessity, at longer intervals and irregular. Before acceptance of cure the patient had anterior urethroscopy, and often a large curved sound was passed in addition. Reinfection was probable in several cases, but every case that had a return of gonococci has been classified as a failure. Cultural methods could not be employed as a test of cure.

Summary

A series of 1,737 cases of sulphonamide-resistant gonorrhoea were treated with penicillin and 93.9% were cured.

The highest percentage of cures in this series was obtained with 100,000 units given as ten intramuscular injections of 10,000 units at intervals of three hours.

Equally good results were obtained in a small additional series of 204 cases with 100,000 units given as five injections of 20,000 units at three-hour intervals.

Less satisfactory results were obtained in a third series of 100 cases treated with four injections of 25,000 units at intervals of four hours.

The lower limit of effective dosage (94.3% cure) was obtained with 60,000 units given as six doses of 10,000 units at three-hour intervals.

Treatment with 50,000 units and 30,000 units produced poor results.

Treatment with sulphathiazole followed by 30,000 units of penicillin did not give satisfactory results in a small series of cases, and the experiment was not pursued.

Seventy-five cases which had failed with primary treatment with penicillin were re-treated with higher dosage of penicillin, and 74 were cured. Subsequent results with cases not in this series suggest that this observation is unduly optimistic. Cases have been observed of persistence of gonococci after 240,000 units given as 15,000 units at three-hour intervals.

Genito-urinary complications of gonorrhoea such as epididymitis responded rapidly to and were completely cured by 100,000 units of penicillin.

This research was made possible only by team work, and a large number of V.D. specialists in C.M.F. co-operated—too many to mention by name. These officers were enthusiastic workers and spared no pains to ensure that the work was done well and records were kept. Lieut.-Col. J. Jeffries and Lieut.-Col. S. H. Bentley and Major Scott Thomson of No. 1 Penicillin Control Team gave invaluable advice and assistance, and organized distribution of the drug. Much of the work was done in tented hospitals with very insufficient assistance, and the R.A.M.C. orderlies who gave the injections deserve the highest praise, for no mishap occurred. I am also indebted to Major-Gen. W. C. Hartgill for his support and for permission to publish these observations.

Lord Samuel, president of the British Institute of Philosophy, the Provost of Oriel (chairman), and the Master of Balliol (deputy chairman) have issued an appeal for support for the Institute, which came of age on April 6. Founded under the late Lord Balfour, its council has been throughout composed of leading representatives not only of philosophy but also of science, of politics, and of industry and commerce. For twenty-one years the Institute has been active in promoting the purposes for which it was founded—to serve as a link between philosophers and the everyday world, and to spread such general understanding as can be reached of the universe and of man's place in it. There have been continuous courses of lectures and popular addresses, and a journal—*Philosophy*—is issued once a quarter. The annual subscription is one guinea, which includes receipt of the journal, and there is no entrance fee. Further information and forms of membership may be had from the Director of Studies, British Institute of Philosophy, University Hall, 14, Gordo Square, London, W.C.1.

TREATMENT OF LEWISITE SHOCK WITH
SODIUM SALT SOLUTIONS

BY

H. CULLUMBINE, M.D., M.Sc.

AND

G. E. P. BOX

(Chemical Defence Experimental Station Porton)

Lewisite poisoning in animals presents a picture of initial haemoconcentration. Due to plasma loss to the soft tissues, followed by a haemolytic anaemia (Cameron and Courtice: awaiting publication). The early picture is indistinguishable from that of shock due to other causes and, as it is readily produced and its severity easily controlled, we have used this method in preliminary studies on the efficacy of sodium salt solutions in the treatment of shock.

Rosenthal (1942-5) has stated that the administration of sodium salt solutions has reduced the mortality in mice suffering from shock caused by thermal burns, trauma, and haemorrhage, the oral or intraperitoneal route being more effective than the intravenous route. Fox (quoted by Rosenthal, 1943) has followed up this work clinically, giving isotonic sodium lactate in large quantities (5-11 litres in 24 hours) by mouth to patients suffering from thermal shock, and all his patients got well. Allen (1943) and Prinzmetal *et al.* (1943) have also reported good results when using physiological salt solutions for the treatment of shock due to thermal burns in dogs and mice respectively. In view of this success in the treatment of shock by large volumes (5-10% of the body weight) of normal saline, it was decided to test the efficacy of such a therapy in lewisite shock.

In the present tests four species of animal were used—viz., mice, rats, guinea-pigs, and rabbits. Subcutaneous injection of lewisite oxide (L.O.) was found to produce uniform and repeatable mortalities in all species. Two methods of assessment were employed. (1) Massive dosages of L.O. given, to produce 100% mortalities rapidly (6-12 hours). Therapies which significantly prolonged the median survival time were tested by method 2. (2) Dosages to produce a high proportion of deaths were given and the percentage mortalities of the treated and untreated groups were compared.

Mice

Mice weighing 20 g. were used throughout. The L.O. was injected subcutaneously in 0.2 ml. of water. As Rosenthal's mortalities are given only for acute mortalities (i.e., the first 48 hours) from shock, our stated mortalities are also acute mortalities. By this means it was hoped that deaths from secondary complicating factors would not complicate the picture.

EXPERIMENT A—Results of Dosage of Lewisite Oxide 9 mg./kg. at Z hours

Quantity of 0.9% Saline given Intraperitoneally (ml.)	When given (minutes)	Median Survival Time in Hours (5 Mice per Group)	Conclusions
Nil		5.9 (25 mice)	
0.5	Z - 30	8.1	(1) 2 ml. saline given. In 30 minutes L.O. produced a significant increase in median survival time (P = 0.03)
0.5	Z	5.7	(2) So d.d. 4 ml. given 2 hours after L.O. (P = 0.05)
0.5	Z + 30	9.3	(3) In general, 4-ml. doses of saline were better the later they were given. 2-ml. doses were better the earlier they were given
0.5	Z + 60	9.3	(4) In general, saline given before L.O. was good (P = 0.05). and 2 ml. saline given before L.O. was good (P = 0.05)
0.5	Z + 120	6.2	(5) All dosages of saline, whether given before or after the L.O., increased the survival time. Saline given at the same time as the L.O. did not

EXPERIMENT D—Dosage of Lewisite Oxide 10 mg./kg. at Z hours

At Z - 30 minutes 2 ml. of the following fluids were given intraperitoneally (30 mice per group):

Normal saline	Median survival time, 5.7 hours
Distilled water	" " " 5.0 "
Unreated .	" " " 4.1 "

Hence (1) The normal saline caused a significant increase in the median survival time (P = 0.02). (2) The water did not cause a significant increase in the median survival time (P = 0.07).

EXPERIMENT E—Dosage of Lewisite Oxide 9 mg./kg. at Z hours. Results from the Intraperitoneal Injection of 0.9% Saline

Total Dose of Saline	Temp of Saline	How Injected	Median Survival Time in Hours (5 Mice per Group)
2 ml.	39°C	2 ml. at Z - 30 min.	8.3
	17°C	"	8.1
	39°C	1 ml. at Z - 30 and Z + 60 min.	7.9
	17°C	"	5.2
4 ml.	39°C	4 ml. at Z + 30 min.	5.5
	17°C	"	5.0
	39°C	1.3 ml. at Z - 30, Z + 60, Z + 90 min.	9.1
	17°C	"	4.8
Nil	—	"	5.2 (25 mice)

Here (1) if a single dose is given, 2 ml. is effective but not 4 ml., and it is of little importance whether the saline is warm or not; (2) if divided doses are given, 2 ml. and 4 ml. are equally satisfactory, but only the warm saline is effective.

From these preliminary experiments it was concluded that, in mice, for the treatment of shock caused by the subcutaneous injection

of L.O., warm (39° C.) normal saline given either as one 2-ml. dose 30 minutes after the L.O. or in two 1-ml. doses 30 and 60 minutes after the L.O. was the best of the therapies tested. Its effectiveness in reducing the percentage mortality from the acute shock of lewisite poisoning was next tested. The quantities used were: 2 ml., given 30 minutes after L.O.; 1 ml., given 30 and 60 minutes after L.O.; 1 ml., given 60 minutes after L.O. (Rosenthal's technique). 1 ml. sodium lactate, given 30 and 60 minutes after L.O., was also assessed, as Rosenthal had reported sodium lactate to be as effective as sodium chloride.

The results obtained are summarized in the following table:

Experiment	Dosage of L.O. (mg./kg.)	Therapy		No. of Mice Used	Deaths in 48 Hours	
		Amount of 0.9% Saline	Time of Admin after L.O.		No.	%
F	4	1 ml.	60 min.	50	11	22
G	4	1 ml.	Nil	50	21	42
	4.5		30 and 60 min.	50	22	44
	4.5		Nil	50	42	84
H	4.5	2 ml.	30 min.	50	19	38
	4.5		Nil	50	33	66
	4.5		30 and 60 min.	20	8	40
I	4.5	1 ml. N sodium lactate	30 and 60 min.	20	5	25
	4.5		Nil	20	19	95
	4.5		Nil	20	19	95

Hence all these therapies produced a significant reduction of the mortality, the sodium lactate being as good as sodium chloride.

Rats

Rats weighing 150 g. were used and the lewisite was produced by the subcutaneous injection of 4.5 mg./kg. of L.O. In mice it has been found that 10% of the body weight (i.e., 2 ml.) of saline was effective when given 30 minutes after intoxication. In rats, therefore, we gave 10% of the body weight (i.e., 15 ml.) of 0.9% saline intraperitoneally 60 minutes after the injection of the L.O. The following 21-day mortalities were obtained:

Untreated group of 50 rats: deaths in 21 days	47 (94%)
Treated group of 50 rats: deaths in 21 days	9 (18%)

Guinea-pigs

A preliminary experiment was carried out to determine the optimum conditions for the administration of the 0.9% saline. 500-g. pigs were used, and to each of them 8 mg./kg. L.O. was given subcutaneously at Z hours. Results:

Total Quantity of 0.9% Saline Injected	How Injected	Median Survival Time in Hours (10 Pigs per Group)
12 ml.	12 ml. at Z + 40 min.	4.6
	12 ml. at Z + 80 min.	4.4
	6 ml. at Z + 40 and Z + 80 min.	2.6
25 ml.	25 ml. at Z + 40 min.	7.5
	25 ml. at Z + 80 min.	3.1
	12 ml. at Z + 40 and Z + 80 min.	1.9
50 ml.	50 ml. at Z + 40 min.	5.0
	50 ml. at Z + 80 min.	4.2
	25 ml. at Z + 40 and Z + 80 min.	2.9
Nil		4.5

From this experiment it was concluded that 25 ml. of 0.9% saline given intraperitoneally 40 minutes after the injection of the L.O. was the best method of administration tried.

A second experiment was then performed, giving 4 mg./kg. L.O. to 500-g. guinea-pigs followed by 25 ml. of 0.9% saline intraperitoneally 40 minutes later. A significant ($P=0.02$) reduction in mortality was produced, as follows:

60 guinea-pigs untreated: deaths in 21 days	31 (52%)
60 .. treated with saline: deaths in 21 days	20 (33%)

Rabbits

When given intraperitoneally, large quantities of normal saline would appear to be ineffective in rabbits intoxicated with L.O. and, indeed, in themselves to be harmful:

Number of Rabbits (2 kg.)	Dose of L.O. at Z hr. (mg./kg.)	Treatment	Deaths in 48 Hours
5	6	6 x 50 ml. N saline at Z + 4, 8, 12, 24, 28, and 32 hours	4
5	6	Nil	4
5	Nil	6 x 50 ml. N saline at Z + 4, 8, 12, 24, 28, and 32 hours	2

The effect of a normal solution of sodium lactate was next examined. Preliminary trials suggested that 2-kg. rabbits were least distressed when two 75-ml. doses were given by mouth with an interval of two hours between doses. Rabbits were therefore injected subcutaneously with L.O. (4 mg./kg.), and to half of them, two hours later, 75 ml. of normal sodium lactate was given by mouth, followed by a similar quantity in a further two hours. The resulting mortalities were:

25 2-kg. rabbits, untreated: deaths in 21 days	22 (88%)
25 .. treated	14 (56%)

This reduction in mortality is significant at $P=0.01$.

Discussion

Rosenthal, using mice, Fox, in humans, Allen, using dogs, and Prinzmetal *et al.*, also using mice, have already reported favourably on the efficacy of sodium salt solutions in the early treatment of shock due to various causes. Large quantities (5 to 10% of the body weight) must be given, and Allen has suggested that shock is a condition of tissue thirst, which can be adequately satisfied only by giving large quantities of physiological saline. Indeed, he intimates that the reason that physiological saline has failed in the past in the treatment of shock is that a sufficient volume has not been given; the presence of haemoconcentration after the administration of saline is not an indication of the uselessness of saline therapy, but merely means that the amount given was insufficient.

Our experiments have shown that large quantities of sodium salt solution do reduce the mortality from shock due to lewisite oxide, but that different species do not respond with equal facility. The order of efficacy of sodium salt solutions in the treatment of shock in the four species tested descends as follows: rats, mice, guinea-pigs, and rabbits. This is also, in our experience, the descending order of the ability of the different species to tolerate large quantities of sodium salt solution.

Rosenthal's work intimates that there is a loss of fluid and sodium to the shocked tissues; our results support this view. We have not had the opportunity of confirming the suggestion that the shocked animal is hypersensitive to potassium, but we agree that the beneficial effect of the sodium administration can be offset by the simultaneous administration of potassium.

Summary

The efficacy of sodium salt solutions in the treatment of shock produced by the subcutaneous injection of lewisite oxide has been assessed in four species of animals—mice, rats, guinea-pigs, and rabbits. It is concluded that large quantities of sodium chloride or sodium lactate solution do reduce the mortality from lewisite shock, but that different species do not respond with equal facility.

Our thanks are due to the Chief Scientific Officer, Ministry of Supply, for permission to publish these results, and to our colleagues at Porton for their advice and criticism.

PENICILLIN: INCREASED STANDARD OF PURITY

The Ministry of Health makes the following announcement. Preparations of penicillin were added to the Schedule to the Therapeutic Substances Act by provisional Regulations in August, 1944. As a result of fuller experience of these preparations it has become necessary to replace the provisional Regulations by new ones. This has now been done by the Minister of Health, the Secretary of State for Scotland, and the Minister of Health and Local Government Northern Ireland. The new Regulations provide for: (1) An increased standard of purity for preparations to be used for parenteral injection, by exclusion of the crude filtrates permitted under the provisional Regulations, and the requirement that penicillin shall be issued only in the form of a dry salt or other dry substance, or in some form approved by the licensing authority. (2) An increase in the minimum potency to 300 units per milligramme for preparation in solid form, and to 2,000 units per cubic centimetre [ml.] for preparations in solution.

Medical Memoranda

Congenital Polycystic Disease of the Liver and Kidneys

The interest of the following case lies in its presentation, with symptoms of hepatic rather than of renal origin. Although the persistently low specific gravity of the urine is evidence of impending renal failure, the symptoms caused by the unusually large cysts which were revealed on laparotomy were superimposed on the more usual clinical picture, and the hepatic condition was serious enough to cause pressure symptoms and transient jaundice. This case was atypical also in the absence of a family history, there being a marked heredo-familial tendency in the occurrence of this condition (Oppenheimer, 1934).

CASE RECORD

A housewife aged 50 was admitted to the London Hospital, complaining of pain and swelling in the upper abdomen, particularly on the right side. One year before admission she suffered from congestion of the lungs and was confined to bed for three months; she was short of breath, coughed up a moderate amount of white frothy sputum, and her legs became swollen. At the end of this illness the blood pressure was high.

Five months after this the upper part of her abdomen, on the right side, became swollen. In a few days the whites of her eyes became yellow and she began to pass black stools and malodorous amber-coloured urine. A week later, at 9 p.m., after a short period of nausea she vomited 14-2 pints (0.85-1.14 l.) of dark-red gelatinous material. She vomited again at 1 a.m. and 7 a.m., the vomitus amounting to about 4 pints (2.27 l.) in all. After two days she still felt extremely weak, and the fronts of her legs became discoloured as if bruised. This discoloration gradually disappeared. Some days later she was admitted to the local hospital, where x-ray investigations were carried out, and a Casoni test gave a positive result. She began to experience a cramping pain in the right hypochondrium, which was relieved by lying down; it recurred at irregular intervals until operation. Her stools and urine became normal in colour and her jaundice disappeared.

During the interval of about four months between her discharge from the local hospital and admission to the London Hospital she felt weak and generally unwell, with intermittent diarrhoea. She had had no previous illnesses related to the condition under discussion, and her family history contained no other record of congenital abnormalities.

On examination the patient was rather ill-looking though well nourished. Her tongue was moist with slight greyish fur. There was no jaundice, anaemia, or any enlargement of the lymphatic glands. Pulse 82, regular, full; no appreciable thickening of arterial wall. Apex beat not palpable; some evidence of cardiac enlargement; heart sounds one and two heard in all areas; third heart sound audible in mitral area. B.P. 215/175. No abnormalities were present in the respiratory and nervous systems. Abdomen: Generalized swelling of upper right quarter; movement during respiration poor; tenderness and some rigidity over the epigastrium and hypochondrium; kidneys and spleen not palpable; liver greatly enlarged, two distinct masses palpable. No ascites. Urine: Specific gravity consistently low (1006), otherwise normal.

Special Investigations.—(1) Casoni test—negative. (2) Intravenous pyelogram: The right kidney began to excrete in 5, the left in 15 minutes. Excretion and concentration poor on both sides. Neither ureter well seen. The pelvis of the right kidney did not appear to be typical of a congenital cystic kidney.

The patient had never been out of the country, and had never kept a dog or lived in close contact with animals. This, together with the negative result of the second Casoni test, made a diagnosis of hydatid cyst doubtful, and it was decided to perform a laparotomy.

Operation.—The liver was greatly enlarged and contained numerous cystic spaces. Both kidneys were enlarged and nodular and contained several cysts, the largest about the size of a walnut. The largest of the liver cysts was situated in the right lobe. This cyst was drained by a cannula inserted through the centre of the anterior surface of the lobe. About 10 oz. (284 ml.) of fluid was withdrawn and the liver was closed by continuous suture. The aspirated fluid was slightly turbid and contained a few small brown coagula. No hydatid hooklets were found.

Post-operative Progress.—The wound healed well. While in bed she was greatly relieved from the cramping pain in the right hypochondrium, although in the convalescent home she complained of pain of moderate severity when she stood upright. Her blood pressure was 160/100 on discharge, as compared with 215/175 on admission.

COMMENT

Congenital polycystic disease of the liver and kidneys is comparatively rare, and is usually manifested in the fourth or fifth decade. In Moschowitz's (1906) series of 85 cases of congenital cystic liver 75 had the associated disorder of the kidneys. However, congenital cystic kidneys are said to have associated congenital cystic liver in only 19%. Associated cysts have been reported in other organs, notably the pancreas, but also in the spleen and ovary, and even in the lung. Many cases have unrelated congenital anomalies; thus polydactylism, spina

bifida, meningocele, hypospadias, anomalies of the bladder, ureters, and renal pelvises, acrania with anencephaly, omphalocele, atresia ani, and haemangioma of the skin have all been reported (Moolten, 1943).

Moolten points out that the disease may follow one of two typical courses, depending on the involvement of the viscera, the limiting factor being the quantity of functioning renal tissue left. He reports the case of a child being born with gross involvement of the liver and kidneys, and which died at 14 days. This he contrasts with the type of case under review, in which death ensues not until the fourth, fifth, or sixth decade, from progressive renal failure. Death is only rarely from hepatic failure, although there may be portal obstruction leading to ascites and splenomegaly.

We would like to thank Sir James Walton and Mr. J. T. Fathi for their encouragement and advice in the publication of this case.

A. P. WATERSON.

Bicuspid Aortic Valve Diagnosed during Life

The case which is here recorded presents an example of the only available method of diagnosis of an aortic valve containing two cusps instead of three.

CASE REPORT

The patient was admitted to St. Bartholomew's Hospital (Hill End, St. Albans) feeling unwell and suffering from excessive perspiration. At this time he was 15 years of age. The past history is significant. He had been seen by me at the King George Hospital at the age of 2, when the classical systolic thrill and systolic murmur of patent interventricular septum were present. He subsequently went to school and remained in reasonably good health, although he had been noticeably subject to breathlessness when playing games with his school-fellows.

On admission to St. Bartholomew's the temperature, pulse, and respiration were 103° F. (39.4° C.), 120, and 30 respectively. He was pale and slightly cyanosed, and looked ill. There was no clubbing of the fingers. The heart presented the following physical signs: the apex beat was rather forcible and was 1/2 in. (1.25 cm.) outside the midclavicular line; a systolic thrill was felt over the third and fourth interspaces to the left of the sternum; the first sound was replaced by a long harsh blowing systolic murmur, which was best heard in the position of the above thrill, but it was conducted to the apex and to the aortic and pulmonary bases; the second sound was heard everywhere, and was normal in character. The spleen was palpable. Petechiae appeared over the upper chest and over the shoulders a few days after admission, but no other evidence of embolism was observed. The blood culture was positive, giving a growth of *Str. viridans*. He was given penicillin by intramuscular drip, the dose being 250,000 units daily, the total course of treatment extending over four weeks. The effect of this was that, although slight fever persisted for a further period of five weeks, rarely above 99° F. (37.2° C.), the patient ultimately became afebrile and was able to get up and about.

The significant clinical event was a diastolic aortic murmur which became audible after the patient had been in hospital for about four weeks. This murmur was distant, high-pitched, and rushing, and was best heard at the pulmonary base and down the left border of the sternum, although it was present over the aortic base. After he had remained afebrile for four weeks he suddenly developed a right hemiplegia and quickly died.

The post-mortem examination revealed the following essential points: general enlargement of the heart; great thickening of the left ventricle; ventricular septal defect; aortic valve bicuspid and showing vegetations on the posterior cusp; extensive haemorrhage into the left internal capsule, apparently from a ruptured mycotic aneurysm.

There was thus no evidence of aortic valve disease either at the age of 2 or when he was first admitted with his subacute bacterial endocarditis. Infection of the aortic cusp distorted it and produced incompetence. In this way the bicuspid aortic valve, although otherwise undiagnosable, was suspected during life, and was demonstrated post mortem.

COMMENT

The above case provides the more obvious example of the development of infective endocarditis in a congenital heart. Many cases of bicuspid aortic valve occur without any associated congenital defect, and in these the additional diagnostic indication present in the patient here described is absent. When infection of an uncomplicated bicuspid aortic valve occurs the diagnosis is suggested by the appearance of the signs and symptoms of subacute bacterial endocarditis in an individual, usually young, who has been previously carefully examined and in whom there was no evidence of heart disease of any kind. In such a case the sudden appearance of aortic regurgitation, together with infective symptoms, is extremely suggestive of a bicuspid valve.

GEOFFREY BOURNE, M.D., F.R.C.P.,
Physician to St. Bartholomew's Hospital.

Reviews

DEVELOPMENT OF PUBLIC HEALTH ADMINISTRATION

Government in Public Health. By Harry S. Mustard, M.D., LL.D. (Pp. 219. \$1.50 or 8s. 6d.) New York: The Commonwealth Fund; London: Oxford University Press. 1945.

"In the past the benefits of modern medical science have not been enjoyed by our citizens with any degree of equality. Nor are they to-day. Nor will they be in the future unless Government is bold enough to do something about it." These words are from President Truman's address to Congress (Nov. 19, 1945) when he introduced his National Health Programme. Dr. Mustard's book is concerned with the history of the influence of "government" on the development of public health in the United States. This publication was sponsored by a committee of the New York Academy of Medicine, on medicine and the changing order. One would hardly have expected that it could have much appeal outside the United States, but Dr. Mustard's treatment of his subject is "national rather than local, general rather than specific, and in terms of trends rather than of events," and the English student of public health administration who reads this book will find much of benefit and interest. The style is compact, workmanlike, and racy, carrying the attention along with effortless ease, and there are so many quotable passages that one regrets the limitations of a short review.

The history of public health in the United States has many lessons for other lands. The struggle between the three "areas" of government—Federal, State, and local (of which the first two have no real equivalent in this country)—resulting in a gradual strengthening of Federal influence; the anomalies of central organization—the fact, for example, that provision for maternal and child health is controlled by the Department of Labor, and completely separate from the Public Health Service; the almost insuperable difficulties besetting any attempts at reform; though the details are often distinctively American, it is easy to appreciate that all these things have had their counterparts in our own history. Perhaps it is a pity that we have experienced nothing similar to the upheaval which followed when the Division of Maternal and Infant Hygiene began operations in 1922, and State health departments first felt the impact of feminine psychology:

"The smugness that existed in many State health organizations was shattered, if not rudely, at least abruptly; precedents, taboos, and sacred relics were brought smashing down; a type of emotionalism, with which male administrators knew not how to cope, arose to plague them. Slovenly programs, and some not so bad, were boldly and openly attacked in one place or another by women's groups, which seemed not averse to calling names, and giving details."

At its best, public health in the U.S.A. is far ahead of this country, but Dr. Mustard is concerned with its shortcomings, and on these he lays stress. It will surprise many who do not realize the vastness of the country to find that nearly forty-eight millions of Americans live in "unincorporated" rural territory—36.4% of the total population. Nearly one-third of the counties, and some 33,000,000 citizens, of the United States are without any Government-supported health services.

This balanced and far-sighted review, by an expert in his subject who is also unusually gifted as a writer, can be recommended to all who are interested in the history of the development of public health administration.

PRACTICE OF MEDICINE

A Textbook of the Practice of Medicine. By Various Authors. Edited by Frederick W. Price, M.D., F.R.C.P. Seventh edition. Oxford Medical Publications. (Pp. 2,034; illustrated. 42s.) London: Oxford University Press. 1946.

The appearance of a seventh edition of "Price's Medicine" at the end of a devastating war must be heralded as another triumph of British co-operative enterprise, and the editor and his contributors, who burned their midnight oil behind the black-out curtains to bring it about, are to be congratulated on their achievement. It will be welcomed by the army of post-graduate students now returning from war to peacetime medicine, for there can be few to deny that Price is the authoritative

text of British medicine. Of the 27 contributors about a third are of emeritus status; but age does not seem to have impaired their accessibility to new ideas, and the book shows as yet no signs of that disintegration of the personality which sometimes overtakes textbooks with advancing years. Hurst's important contribution shows all his vigour and flexibility, and we are reminded once again of his unique place in British medicine. It will be hard to fill the gap his death has made. The seventh edition is fortunately no longer than the sixth, and the editor has clearly insisted on dynamic reconstruction rather than mere hypertrophy; but at more than 2,000 pages it is literally a weighty tome. It is therefore to be hoped that the undergraduate student will use it as a reference book, in which he studies the diseases of which he has personal experience, rather than as a systematic account of medicine through which he is condemned to labour.

Advances since the last edition have been mainly on the therapeutic side, as, for example, penicillin, the newer sulphoamides, the proper appreciation of mepacrine in malaria, thiouracil in exophthalmic goitre. On the clinical side, the chief advance is the recognition of the Rh factor in the blood groups and the consequent explanation of the aetiology of haemolytic disease of the newborn. But if these are the major advances, there are a host of minor ones, as shown by the detailed list of alterations in the preface. It would be impertinent to pretend to criticize this edition line by line without having lived with it and worked with it for months, as we have learned to rely on previous editions. At first glance, however, it appears as reliable and comprehensive as ever, and only those who do not realize how long it takes to see a book through the press these days will grumble that it does not contain the final harvest of knowledge of penicillin. The editor and the publishers have performed a great service for post-war medicine—have performed it so successfully, in fact, that there will soon be a demand for an eighth edition and for contributors of the new generation to work under the skilful co-ordination of Dr. Frederick Price.

PYELONEPHRITIS OF PREGNANCY

Hydronephrosis and Pyelitis (Pyelonephritis) of Pregnancy. Aetiology and Pathogenesis. An Historical Review. By H. E. Robertson, M.D. (Pp. 332; illustrated. 25s.) Philadelphia and London: W. B. Saunders Company.

This illustrated monograph is for the most part a historical review of an important and fascinating subject. It is now known that some degree of dilatation of the ureter and renal pelvis occurs in every pregnant woman, and it is unanimously accepted that in 5 to 7% of these infection occurs at some stage of the pregnancy. In spite of the vast material thus provided for study it is somewhat humiliating to have to admit that such fundamental questions as why the dilatation occurs and how the invading organism is transmitted cannot as yet be answered with absolute authority. No one who is interested in this subject should fail to have a copy of Dr. Robertson's excellent review. In it he discusses nearly 1,000 relevant publications dealing with all aspects of the subject—anatomical, physiological, endocrinal, biochemical, and radiological. The gradual accumulation of knowledge is traced through the records of the years and makes most interesting reading, but the critical reader is reminded repeatedly of how much there is still to be learned.

This book has justified its publication by the scope of its historical survey, but if it succeeds in arousing fresh interest in an aspect of pregnancy which is too often ignored, then its ultimate effect will be far-reaching and the considerable labours of its author will be richly rewarded.

SEX EDUCATION

The Practice of Sex Education. By Dr. Eustace Chessier and Zoë Dawe. (Pp. 157. 10s. 6d.) London: Medical Publications, Ltd.

This useful book is divided into two parts. In the first Dr. Eustace Chessier deals with the subject generally. He stresses the importance of proper sex education and draws attention to its extreme imperfections at the present time. In his chapters on the child, the parent, the teacher, and the school he gives examples of the ill-effects of the usual evasions, and makes a good point that children should be taught the proper scientific names of the genital organs and their various parts, since difficulties often arise due to ignorance among the elders of anything

but inappropriate slang terms. In his last chapter he gives a very brief description of the physiology and Freudian psychology of sexual development. Whether the uninitiated will grasp the latter difficult subject is doubtful.

In the second part Miss Zoë Dawe describes a course of reproductive biology which she gives in schools. It is a moot point whether school is the place where first sexual instruction should be given, but Miss Dawe's course is in itself admirable, and would be specially valuable if the parents had already done their duty in answering the child's questions frankly and truthfully as they arise. Two chapters at the end are very interesting. One enumerates the sort of questions asked by children of the 12-14 age group, either by word of mouth or in writing. The other gives selections from essays written by the girls commenting on Miss Dawe's course.

Of the many books on sex education which are appearing this is one of the most valuable.

PAEDIATRICS

The 1945 Year Book of Pediatrics. Edited by Isaac A. Abt, D.Sc., M.D. With the collaboration of Arthur F. Abt, B.S., M.D. (Pp. 443; illustrated. 95s or 18s.) Chicago: The Year Book Publishers; London: H. K. Lewis and Co.

Once again the two American paediatric professors, I. A. Abt and A. F. Abt, have edited a valuable collection of abstracts, and the *1945 Year Book of Pediatrics* is well up to standard. It is perhaps regrettable that the journals forming the basis of the book are essentially confined to the English-speaking world, but in defence it may be argued that only in such parts of the world has it been possible to continue original work in this subject. An adequate proportion of the abstracts have their origin in Great Britain. The editors have added, as usual, their helpful comments in the form of notes at the end of the abstracts. It is satisfactory to observe that although, naturally, the new advances of chemotherapy have their place they have not been allowed to swamp the volume or upset the balance. There are other important subjects, in regard to diagnosis and treatment, which receive due mention. The work contains a "quiz" of twenty questions, and the reviewer regrets to say that he did not secure a pass mark before he read the book. This should be an indication of the amount of new material presented—and in a manner which is easy to assimilate.

Notes on Books

The fourth edition of *Essentials of Body Mechanics in Health and Disease*, by Drs. JOEL E. GOLDTHWAIT, L. T. BROWN, L. T. SWAIN and J. G. KURYS, the famous Boston orthopaedic team, is opportune, when we are hearing and thinking so much of the rehabilitation of those who have succumbed to the strains and stresses of war both at the front and at home. We cannot be too often reminded that structure and posture of the body influence the function of every system and every organ, and this simple guide to the maintenance of good posture and correction of bad posture will keep these important truths in the minds of all doctors if they study it. In this edition the chapter on foot-strain has been recast so that it is a simple and clear exposition of what goes wrong and how to get it right. The new chapter on geriatrics merely calls attention to the fact that almost all the disabilities of the ageing interfere with body balance, that restoration of this so far as may be possible mitigates these afflictions to a considerable extent, and that their onset may perhaps be indefinitely postponed if correct body mechanisms have been maintained throughout life. The book is published in London by J. B. Lippincott Company at 30s.

In *Gas and Air Analgesia in Midwifery* (Staples Press Ltd; 5s.) Dr. G. H. T. STOVIN makes an attempt to give the reader more details than are found in similar textbooks, of the manufacture of nitrous oxide and of the mechanics of the common analgesia machines. The administration of gas-and-air analgesia is described well enough, but the book on the whole falls between two stools. The illustrated and well-written section on apparatus is likely to be too much for most midwives, while medical readers may feel that the clinical section could be expanded. The book's chief appeal will be to those who want to know a little more about the "innards" of analgesia machines.

E. and S. Livingstone Ltd., of Teviot Place, Edinburgh, have published a seventh edition of *A Pocket Medical Dictionary*, compiled by Miss LOIS OAKES with the help of Prof. Thomas B. Davie. This little book made its bow in 1933 and has gone through six editions and three reprintings. The price is 4s., plus 4d. postage.

Preparations and Appliances

A GAG FOR USE DURING ELECTRIC CONVULSION THERAPY

Dr. B. ANDRATSCHEKE, Mr. J. H. D. MYATT, L.D.S., and Dr. C. H. ROGERSON, F.R.C.P., write from the Cassel Hospital for Functional Nervous Disorders:

One of the most troublesome complications of electric shock therapy is the damage to the teeth which sometimes results from the tight closure of the jaw during convulsion. When a semi-rigid gag such as a padded wooden spatula is used, loosening and even splintering of the teeth which receive the pressure may occur.

At first we thought to overcome this problem by a gag made of a rolled-up piece of rubber cut from an old hot-water bottle. Obvious damage still, however, occurred, particularly when one or two teeth had to bear the brunt of the pressure. Nor was this all, for one of us (J. H. D. M.) was able to demonstrate that in several instances there were serious remote effects of trauma in the form of periodontitis, and later devitalization of teeth which had shown no obvious injuries at the time of treatment other than a little bleeding from the gum margins.

We realized that a new type of gag was needed which would fulfil the following essential conditions: (1) It must secure an equal distribution of pressure over all teeth. (2) It must prevent accidental biting of tongue, lips, or cheek. (3) It must be constructed of a shock-absorbing medium which would remove the dangers of blow and pressure trauma, even in mouths presenting irregular occlusal planes.

Taking these features in order: (1) and (2) We constructed a gag to what we considered the required shape, in dental wax on a metal framework. By repeated trial in the mouth this was modified to an optimum shape. This shape is, roughly, that of two shallow lower impression trays placed back to back, in one piece, tapering towards the back to conform to the occlusal surfaces. The raised flanges prevent any accidental biting of tongue lips or cheek. (3) The gag was made in soft "vela" rubber, which has proved a satisfactory medium. One of the new soft plastics may, of course, have advantages over rubber.

The gag is easy to insert, it is, of course, placed in position before the current is applied. It is almost entirely self-retaining, so that the assistant's attention can be directed towards supporting the lower jaw to prevent the dislocation which sometimes occurs during the initial wide-opening. There is an adequate airway through the teeth and round the gag which can be improved if necessary by hooking back the angle of the mouth with the finger. We are, in any case, in the habit of administering oxygen through a nasal catheter to all patients showing cyanosis after the convulsion.

Extended clinical trial has demonstrated that it fulfils our required conditions. It can be constructed by any good dental mechanic.

MICROMETER SYRINGE

The "Agla" brand micrometer syringe was developed at the Wellcome Physiological Research Laboratories, Beckenham (*Biochem. J.*, 1925, 19, 1111) for use in experimental techniques requiring the accurate measurement of very small amounts of fluid. It consists of a specially made hypodermic syringe with a standard needle mount, attached by a rigid holder to a micrometer which operates the plunger. By its use volumes as little as 0.001 ml. can be delivered with an accuracy of ± 0.00005 ml. Typical uses are chemical micro-titrations, serological titrations, injections of laboratory animals with small doses, measurements of small volumes for Langmuir trough experiments, and surface tension measurements. The distributors, Burroughs Wellcome and Co., 12, Red Lion Square, London, W.C.1, hope to be able to resume deliveries of this instrument within the next few months, and invite inquiries. Orders will be executed in rotation when supplies become available.

Allen and Hanburys Ltd. announce the introduction of a new product "fel-evac," a synthetic fatty meal for use in cholecystography to promote the emptying and consequent contraction of the gall-bladder.

SATURDAY APRIL 20 1946

THE PRESS, THE MINISTER, AND THE BILL

In any dispute both parties believe the right to be on their side, at least in the early stages. When tempers have cooled after the initial clash each party may, even though grudgingly, admit there is something in the other man's point of view. Both then gradually discover a common ground on which to agree and, if they possess more than the wisdom of the serpent, put on one side points of difference when they are regarded by each as fundamental. This is what is known as compromise, and has hitherto been held to be peculiarly an English virtue. The most regrettable and distasteful aspect of any dispute, major or minor, is what we might call the period of misrepresentation. In so far as the present controversy over the National Health Service Bill is concerned, the medical profession has seen its views and statements misrepresented in some organs of the popular press and by individual spokesmen for political reasons.

Apart from deliberate misrepresentation of fact, there is the insidious form that comes from stating only or largely that side of the case which one favours. The medical profession cannot but feel disturbed when it finds the most powerful organ of public opinion in this country—the *Times*—lending its authority to a one-sided presentation of the issues now before Parliament, the profession, and the people. Finding in our esteemed contemporary support for its own policy, it uses the ammunition for its own big guns, and ignores the different expression of opinion voiced in these columns on the Bill as a whole and on the hospital question in particular. Thus the non-medical and informed public which looks to the *Times* for a balanced presentation of majority medical opinion on an important issue is not, we think, provided with it. Instead it finds an attack upon the B.M.A. in this form: "Doctors and laymen alike have naturally looked to the B.M.A. Council's statement on the Bill to learn what issues might be held to justify talk of a fight for medical freedom 'should Parliament prove obdurate.' The document contains no such issues." Yet the *Times* admits the proposals in the Bill mean the nationalization of hospitals, and ignores the argument advanced in these columns that a general-practitioner service on a part-salary basis in health centres owned by local authorities will nationalize general practice. It seems to approve of "the course favoured by the *Lancet*," which "would seem to imply a similar nationalization of all the other medical services"—i.e., of those services in addition to the hospital service. It is just because of these implications that the B.M.A., representing 51,000 doctors, foresees the possibility "of a general refusal of doctors to enter the new service."

A criticism of the B.M.A. which finds expression in our correspondence columns, and in debate and conversation, is that the Association has no constructive plan or views of its own. Some medical men are genuinely perplexed, and an analysis of the position may be clarifying. In 1938 the B.M.A. placed on record its constructive proposals in a pamphlet entitled *A General Medical Service for the Nation*, which, briefly, advocated the extension to the dependants of the insured population of the medical benefits under the N.H.I. Acts, and the expansion of this scheme by the inclusion of consultant, specialist, and institutional services—in other words, a comprehensive health service for the families of the wage-earners. After the war began the B.M.A. set up a Medical Planning Commission, which published its Draft Interim Report shortly before the appearance of the Beveridge report. In view of the fact that Assumption B necessitated an investigation by the Ministry of Health into the medical services of the country, the Association decided not to proceed to a final report of its own Commission but to make its contribution to the Ministry's inquiry if called upon to do so. If we may be wise after the event, this decision may have weakened the Association's position in controversies that have flowed from the publication of the Beveridge report, Mr. Ernest Brown's abortive White Paper, Mr. Willink's White Paper, and Mr. Aneurin Bevan's Bill. Confronted with these successive Government pronouncements the B.M.A. and the medical profession have naturally been put on the defensive and in the position of having to criticize this and that aspect of them for fear they should go by default. The profession has been tactically at a disadvantage, and its antagonists on the platform and in the Press have used this situation to misrepresent it.

It may, therefore, still serve some purpose if we state as plainly as is possible what the position of the B.M.A. is at this moment, bearing in mind that policies may be changed by the Special Representative Meeting in the beginning of May. First of all we have, in common with Mr. Bevan and his predecessors, the aim of providing a comprehensive health service—or perhaps we should say medical service, because health will not come out of any service but out of the conditions that make for health. Second, we agree that all the resources of modern medicine should be at the disposal of everyone: we differ on the means of achieving this. Third, we approve of the Minister's plan for administering the hospital service on a regional basis, and of his proposals for national laboratory and transfusion services.

What are the points of disagreement? There is disappointment that the Minister has not been able to integrate in his Ministry the various services still administered by other Government Departments. The administrative separation of hospital, general practitioner, and clinic services makes, in the view of the B.M.A., proper co-ordination of the work of doctors taking part in them difficult. What is worse, there seems to be a sharp separation of the general practitioner from the hospitals. The failure to give details of the composition of the Regional Board, and the failure to make the Central Health Services Council a really effective body, are further matters on which the Minister is criticized.

If the Bill is looked at as a whole and in relation to the future evolution of the medical profession, there are two features which the Council of the B.M.A. finds not only disappointing but profoundly disturbing. The first is the proposal to disinherit the voluntary hospitals, and to deprive local communities of the part they should play in the development of local institutions. With the ownership of all hospitals vested in the Minister of Health, given absolute power subject to Treasury discretion, the hospitals of this country will in effect be run by the civil servants of the Ministry—for they are permanent, while the Minister is but a temporary figure. A State hospital service means in the long run that medical men working in it will be wholly or partly State employees working under Civil Service direction. State ownership of hospitals can mean nothing less.

The future general practitioner will, it is proposed, practise in the public service in an area only with the permission of a Government committee, be paid in a substantial part by salary, and conduct his practice in and from a health centre owned and administered by local health authorities. This, it is not unreasonable to assume in view of the Labour Party's declared policy, is the first step to a whole-time salaried basis.

Considering the hospital and the general practitioner plans together, we cannot avoid the conclusion that they form the nucleus of a whole-time salaried State medical service. We may grant that in opposing this conception some men are actuated by selfish motives, just as some of those supporting it are actuated by a desire for power. But doctors individually and collectively have a deep-rooted distrust of authoritarianism in medicine, are not inspired by the effects upon medicine of powerful administrations, and see nothing but harm in a system which introduces an official between the doctor and his patient.

What, then, is left on which the medical profession can work out a constructive scheme in co-operation with the Minister of Health if he will seek this? If the doctor is to put his back into his work let him be rewarded according to his merits and exertion. Among the many motives that impel a man to take up medicine the economic motive is one—and not an unworthy one. Medical men are as unequal in their native abilities as any other group of men: their genes see to this. To attempt to treat them as equal by giving them equal salaries and pooling capitation fees is to attempt to treat them as mass-production units, and the corollary of this is that the patients will come to be treated as so many units of disease. This will lead to unending dissatisfaction, frustration, and resentment—and bad medicine. We would, therefore, suggest that the Minister drop his salary proposal and see that doctors are remunerated on a capitation basis. As to health centres, we suggest they should be started in certain areas, and that different types should be set up. The advances of medicine which are said to necessitate the development of health centres are not in the clinical field but in the laboratory. Therefore to group clinicians will in itself be no solution of the problem. What the practising doctor needs above all is access to the facilities offered by medical science and personal contact with and advice from the men expert in the various branches of this science—the bacteriologist,

the pathologist, the biochemist, the radiologist and radio-therapist. What needs grouping are the services provided by these men, and the most suitable centre for the grouping is the hospital, provided that every practitioner in the country has a properly equipped hospital within easy reach of him and his patient—and modern communications should not make this impossible in a compact country like England. The general practitioner does not so much want consultation with another practitioner in a health centre as with the man who has expert knowledge he does not possess himself. If general-practitioner health centres will benefit the patient and add to the convenience of the doctor, then their evolution is to be desired. But the incentive to excel professionally needs an atmosphere of freedom.

The same atmosphere of freedom and independence is even more necessary in the hospital. Each hospital must be free to work out its own salvation within the general framework of the hospital service. Liberty to develop is often willfully misrepresented as licence to exploit. If liberty is curtailed, then one sure result is that licence will increase. Each hospital in a region must obviously fit into the general pattern; its function and the scope of its services must be defined. The staffing proposals of the Minister, with the setting up of selection committees, will ensure that local favouritism or nepotism will not exert its unhealthy influence. But to cut off the current of local affection and pride in local institutions is to sever something which is really valuable in our national life.

The present Minister of Health has never been cowed by majorities or afraid to express his individual view. The medical profession likewise should not be cowed by the large majority the Minister has behind him in the House of Commons, and we may hope that the Minister may yet negotiate on points of difference between him and a profession which sincerely holds them. Democracy is discussion, and the medical profession wants to discuss these matters before the Bill becomes an Act under the terms of which it will work with reluctance and dissent.

ENCEPHALITIS AND ENTOMOLOGY

In North and South America, in Africa, in the Far East of Asia, and in European Russia there exist forms of encephalitis caused by viruses and transmitted by mosquitoes or ticks. What are the dangers that with the development of aviation these diseases may be spread from endemic areas to other parts of the world and, in particular, to Britain? Health authorities are alive to the danger of the spread of yellow fever by infected mosquitoes carried in aeroplanes. Ought they to be worrying also about a whole series of other virus diseases? Of supreme importance is an understanding of the oecology and epidemiology of the group, for thus alone can we foresee and guard against possible disasters; we therefore read with deep interest of the work carried on in the last few years, especially in America and Russia, and lately reviewed by Drs. Hammon and Reeves.¹

The only arthropod-transmitted encephalitis yet recognized in Britain is louping-ill, a serious disease of sheep, especially along the Scottish border; this is carried by a tick, *Ixodes ricinus*. The virus is known to be pathogenic for man, but is not normally a cause of human disease in Britain. It is, however, serologically very closely related to the virus of spring-summer encephalitis of the forested regions of the Eastern U.S.S.R., and may even be a biological race of that virus. The Russian virus, also tick-borne, is of importance as a cause of encephalitis of man, not of sheep. A tick-borne encephalitis of man occurring in the far east of the U.S.S.R. is said to be caused by a different virus.

Of encephalitis viruses carried by mosquitoes there exists now a terrifying array. We have St. Louis encephalitis and Western equine encephalomyelitis of Central and Western North America, Eastern equine encephalomyelitis, and, in South America and Trinidad, the Venezuelan equine encephalomyelitis. All of these can cause encephalitis in man, and the first two in serious numbers. At least two other, yet unnamed, viruses have been isolated from wild-caught mosquitoes in Colombia and California; they have not yet been certainly implicated as responsible for human disease but can cause encephalitis in mice and other rodents, and neutralizing antibodies against the Californian one have been found in the sera of some encephalitis patients. Across the Pacific, the Japanese B encephalitis is said to have caused over 12,000 human deaths in Japan between 1924 and 1937. It occurs also in China and in Eastern Siberia, where the Russians call it "autumn encephalitis." Now that there are many U.S. troops in Japan and China authorities in the U.S.A. are disturbed at the possibility of the addition of yet another to their already formidable collection of encephalitis viruses in America, for the necessary mosquito vectors are present there. In Central Africa also a virus, West Nile virus, has turned up, closely related to the St. Louis and Japanese B viruses; experimentally it is transmissible by the mosquito *Aedes albopictus*, and serological tests suggest it may infect man over a wide area. Though it causes encephalitis experimentally in mice and other animals it is not known whether infection of man is ever accompanied by encephalitis.

The three varieties of equine encephalomyelitis came to our attention because of the losses inflicted on horses, and only later were human infections recognized; it is now believed that the viruses far more commonly infect birds, and especially domestic fowls. Men and horses may develop encephalitis if bitten by infected mosquitoes, but such occurrences are accidents, unrelated to the normal life-history of the viruses. The mosquitoes particularly concerned in transmitting the St. Louis and Western equine viruses are *Culex tarsalis* and *C. pipiens*, both of them species known to feed predominantly on birds. The viruses have been repeatedly recovered from wild-caught mosquitoes (on 75 occasions for the Western equine virus).

A *Culex*-fowl cycle, however, will not adequately cover the life-history of the viruses as we know it. To be satisfied that we understand the oecology we must be able to visualize a mechanism by which the virus survives from year to year. This might be in a chronically infected

mammal or bird or in a persistently infected arthropod vector. No one has yet succeeded in showing that chickens or other birds can serve as chronic or latent carriers of the infection. Further, no virus has been recovered from hibernating mosquitoes (5,429 have been tested for St. Louis virus); so the mechanism of survival of the virus through the winter is quite obscure. Nor is there any evidence suggesting that the St. Louis virus can be transmitted through the egg to the progeny of an infected mosquito. Search has therefore been made for other possible arthropod vectors. Experimentally, dog-ticks (*Dermacentor variabilis*) can be infected and transmission through the egg (transovarian infection) occurs; but no naturally infected ticks have ever been found. Quite recently the viruses of both St. Louis and Western equine encephalomyelitis have been recovered from chicken mites, *Dermanyssus gallinae*, and the possibility of transovarian infection in this mite has been shown for the former virus. Even so, this mite may turn out to be a misleading clue, for transmission by the bite of these mites has not yet been accomplished; moreover, virus has only exceptionally been found in mites though readily revealed in mosquitoes in the same localities. It now seems that we must probe deeper still into natural history. Just as human and equine infections proved to be incidental to an infection of poultry, so it now seems possible that the infection-cycle in the fowls may be something superimposed on a basic life cycle with some other vertebrate-arthropod sequence. Possible clues are afforded by the finding of infected prairie chickens, pheasants, pigeons, ground squirrels, and deer in the wild state. Domestic fowls are, from the evolutionary standpoint, very recent introductions to North America and most unlikely to be the original hosts, since the North American viruses have not been recognized in Asia, from which our domestic fowls ultimately derive.

In Britain we have men, horses, fowls, and potential *Culicine* vectors; so we do well to be on the watch for the viruses. But we may reasonably hope that the essential virus reservoir will prove to be absent over here. We may take comfort from knowing that the Western equine encephalomyelitis virus does not readily spread eastwards across the American continent, nor the Eastern one westwards. But we should be happier for seeing the problem of the natural history of these diseases well and truly settled.

AIR DISINFECTION

The disinfection of the heavily polluted air which we still have to breathe in certain places remains the greatest sanitary reform yet to be achieved. No doubt air-conditioning and more spacious design will play the major part in this reform, but circumstances are likely to remain in which chemical disinfection will also be advisable. Much has been discovered about possibilities in this direction in the past few years, and it is satisfactory to see that the subject is not being neglected. The use of glycols has passed beyond the small-scale experimental stage in the U.S.A. and is being applied in rooms or buildings of considerable size, with careful observations on the results in preventing the spread of air-borne infection. Such a study is reported

by E. Bigg, B. H. Jennings, and I. C. W. Olson¹: this was conducted in barracks where four identical pairs of dormitories served as test and control areas, the former being supplied throughout the night with triethylene glycol vapour to produce an atmospheric concentration of about 0.0025 mg. per litre (i.e., 1 part in 400,000,000). Needless to say, none of the inhabitants complained of any unpleasant effects. Even this very low concentration reduced bacterial counts obtained from the air, and there is evidence that it also reduced the spread of infection. This is of three kinds: the hospital admission rate among men from the test dormitories was lower than that from the controls; the spread of an epidemic of mumps was apparently partly checked, and there was a marked reduction in the number of men from whom throat cultures grew haemolytic streptococci. By analysing these carriers into "losers," "gainers," or "keepers," and plotting their positions in the dormitories on diagrams, it is made evident that the spread of this infection must have been largely prevented: there were only 7 gainers in the test series but 32 in the control. Apart from this feature the figures are not impressive, but they are at least promising; it must be borne in mind that nothing was done in other parts of these buildings to control the spread of infection during the daytime.

The halogens are another class of air disinfectant which shows promise. Most work in this direction has been done with chlorine in some form, but Joyce D. Stone and F. M. Burnet² have used iodine vapour in a careful experimental study of the destruction of influenza virus suspended in the air in the form of minute droplets. Mice were introduced into the experimental chamber after disinfectant treatment as an indicator of its efficacy. Almost immediate inactivation of the virus was produced by an atmospheric iodine concentration of 0.1 part per million, whether the virus was suspended in Ringer's solution or human saliva; on the other hand, if the droplets were desiccated by reducing humidity with calcium chloride an iodine vapour concentration 40 times greater was only partly effective. Iodine is too expensive for general use in air disinfection, but these authors make the interesting suggestion that a gauze mask impregnated with iodine might be a valuable safeguard to medical personnel dealing with highly infectious and dangerous diseases, such as pneumonic plague, pandemic influenza, and psittacosis. In experiments of another kind chlorine was found to be about as effective as iodine in destroying influenza virus. The chlorine disinfectants are cheap enough, but their utility for general purposes is likely always to be limited by their corrosive action on metals.

THE USE OF TUBERCULIN

When the Ministry of Labour received powers to "direct," compulsorily, both nurses and domestics into tuberculosis institutions an interesting administrative problem arose. Though it is doubtful whether this legal power of "direction" has been used to any extent if at all, its consequences have been significant. The Ministry desired a quick way of deciding whether a particular individual could work with safety in the environment of a sanatorium. Not unnaturally, from the point of view of the layman, the tuberculin test was thought to provide the answer. Why not tuberculin-test all individuals before "direction"? Those who understand the nature and mechanism of the tuberculin test realize that this is the very thing which it does not do. Tuberculin does not enable us to diagnose

clinical tuberculosis, in adults at least, nor does it afford any reliable guide as to who should, or should not, work in a sanatorium. Nevertheless, the question of how tuberculin should be used for this purpose was referred to a subcommittee of the Ministry of Health's Standing Advisory Committee on Tuberculosis, under the chairmanship of Dr. James Watt, and it has now presented its report.

There is nothing new or revolutionary in this document, but it is interesting to note that the committee recommends Koch's Old Tuberculin rather than the newer purified protein derivatives of Seibert and Long. The latter, which is extensively used in the U.S.A., is not at present manufactured in this country, but can be imported. The committee recommends three graduated doses of Old Tuberculin, used by the Mantoux method of intracutaneous injection. Recommendations are made to secure standardized syringes, and a regular technique which can be used by different doctors with comparable results.

A positive tuberculin reaction indicates, of course, that the individual has undergone primary infection with the tubercle bacillus, and this infection is in most cases a benign symptomless process. A negative reaction indicates that tubercle bacilli have never successfully invaded the tissues. Such facts have long been accepted, but it is their interpretation and administrative consequences which called for careful reconsideration. The committee rightly lays stress on that phase of the individual's life when the tuberculin reaction is changing over from negative to positive. This phase, as Scandinavian work has shown, is the risky one. It is rightly asked whether, in view of the hazards, nurses who are tuberculin-negative should be admitted at all to sanatorium staffs. The committee states categorically its belief that the suggestion to exclude Mantoux-negative nurses is in the interests neither of the nurses nor of the public. In future the proportion of Mantoux-negative reactors in the community is likely to increase, due to our better social control of tuberculosis, and this will occur particularly in the age group from which nurses are recruited.

As for the nurse's own interest, it is clear that a sanatorium nurse is in a much better position than a nurse in a general hospital if a threat of clinical tuberculosis develops. She enjoys on the whole better hygienic conditions while working in the wards, and preventive measures are more likely to be taken. In the future the use of B.C.G. may greatly ease this problem. Nevertheless, careful recommendations are given for safeguarding the health of Mantoux-negative nurses. These recommendations include: (a) Repeating the Mantoux test every three months until it becomes positive; (b) x-ray films of chest on entry and at regular intervals; (c) special care when the Mantoux test changes from negative to positive; (d) monthly body-weight records under comparable conditions; (e) the care of the nurse's health to be the responsibility of the senior member of the medical staff. Finally, it is recommended that the examination of individuals to be "directed," should not be done by the local authority's tuberculosis officer but by the employing sanatorium. Too elaborate an inspection tends to give the impression to the candidate that tuberculosis nursing is a much more hazardous occupation than it is.

Before long we imagine the administrative procedure of "direction" will be of historical interest only, as in future no woman will be compelled to work in a sanatorium against her will. If the procedure has done no other good it has at least brought the tuberculin test back into favour, not as a means of diagnosis or of treatment but as a measure of preventive work in tuberculosis, such as was preached by Sir Robert Philip twenty-five years ago.

A VISIT TO AN INDIAN LEPROSY COLONY

BY

P. P. NEWMAN, M.B., Ch.B.

The Settlement covered about fifty acres (20 hectares), most of which was farmland. The hospital was a low building in a central position, with verandahs connecting each ward. It had a dispensary, though many of the shelves were empty; an operating theatre, scrupulously clean, but lacking suitable lamps and equipment; and also a laboratory, where exceedingly skilful work was performed. Apart from the routine of bacteriological investigation, the staff had collected a whole series of pathological specimens, which they themselves had prepared and mounted.

We were shown some of the case-sheets. A full history of each patient was taken at the clinic with special reference to the family and other sources of contact. Nearly everyone had some family connexion, but the incidence of long-neglected disease was rapidly declining. The people were becoming "leper conscious" and would seek advice and treatment on the first appearance of symptoms. Many of the cases were self-diagnosed, though microscopical section of the skin around the nodules was done as a routine. Little children would come up of their own accord to show a small lesion on the skin they had noticed, and it was these early cases which responded most successfully to treatment. A child born of a leper did not usually develop the disease if it was taken away from the mother soon after birth. The children were kept segregated in a school on the same Settlement, and the parents were allowed to visit them once a week. Eventually these children would lead ordinary healthy lives, perhaps even healthier than the average individual in India, on account of the extra care taken over them. In some instances, where the mother was non-infective, she was allowed to continue to look after her baby while under observation.

The case-sheets carefully recorded the progress of each patient, with accurately illustrated charts of the lesions and of the extent of anaesthesia. Cotton-wool was found too light to detect superficial sensation, and small feathers were used instead. From a glance, it appeared that nodular lesions affected mainly the face and limbs, while the anaesthetic areas were distributed on the trunk. The standard treatment was by injection of hydnocarpus oil in 4% creosote or thymol; results on the whole were good. As many as fifty injections were given with quarter-inch (6 mm.) needles into the skin around the leprosy areas, in addition to daily intramuscular injections. Cases were studied over a number of years and there were very few relapses, except in those who contracted venereal disease.

Unfortunately, syphilis was a very frequent concomitant of leprosy. It not only lowered the general resistance of the patient but impeded the action of the drug, and, of course, the two diseases had to be treated concurrently. Tuberculosis was another complication, and such cases could be highly infectious. There was only a small portable x-ray apparatus available, so that to differentiate this disease from leprosy reliance had to be placed on bacteriological examination. Because of the similarity of the causal organisms, one had, finally, to rely upon the clinical picture. However, before a case was regarded as non-infectious the doctor had to be satisfied that the organism was absent from twenty consecutive examinations. Then, in the disease-arrested stage, there was a follow-up routine extending over several years.

The Surgery of Leprosy

One had only to do a round of the wards to be struck by a sense of unparalleled achievement and of devotion to humanity. One saw very few cases that were either repulsive or hopelessly riddled with disease. Death from actual cachexia was rare. The disease began as a rule with a simple skin eruption on the arm or leg in the form of nodules, either under the skin or above it. Some cases presented raised vesicular patches. There might be some loss of sensation over a wider area, but early treatment gave very promising results. More often the disease

took the form of an insidious contraction of tissue in the fingers and toes, accompanied by a localized area of anaesthesia. Because of the loss of the protective and nutritive function of nerves, complications following injury added to the process, with all the sequelae of secondary infection. In any case, leprosy is relentless in its attack, and very soon there was considerable loss of tissue with subsequent deformity. It was not true to say that digits dropped off from the limbs; rather it was the persistence of a contracting process that gave, however, the same end-result.

The leper then was a subject for amputation. Many hundreds of those people could demonstrate some form of surgical intervention, and, in spite of the inadequacy of equipment, a high performance of operative procedure was maintained. The scars healed well and without much evidence of sepsis. In spite of the loss of half a foot, patients were able to walk with reasonable effectiveness and stability. It was found that when a metatarsal amputation was designed, the disease had often penetrated into the tarsus and a more radical operation became necessary. Yet the degree of mobility and stability after those operations on the feet was out of all proportion to the teachings of textbooks. When it attacked the face, leprosy could be the most devastating of diseases. Some of the victims were unquestionably horrible sights. The nasal cartilages suffered primarily, but even here attempts were made at plastic treatment which could bear comparison with that of the best centres in Europe or America. The men who performed this work were accomplished clinicians, surgeons, and physicians all in one. They had also to be specialists in orthopaedics. Abscesses were frequent in bones and fractures occurred readily. Of the other complications, iritis was the commonest, though actual blindness was rare. Sometimes the disease affected the scalp, producing an alopecia, but apart from a definite thinning of the eyebrows, loss of hair was not an outstanding feature. Leprosy did not seem to precipitate cardiac or gastric disease, and, except for associated syphilis, the mental picture was normal. Some cases of hysteria were present, but leprosy did not adversely influence the intellect. The other form of the disease was essentially an interstitial neuritis, and the ulnar nerve of one or both arms was nearly always affected. There was a round-cell infiltration and thickening of the nerve with resultant wasting and paralysis. Decapsulation sometimes gave marked clinical improvement.

There were about 700 patients, 80 of whom were ward cases; 10,000 treatments were given annually. The disease respected no particular caste, but appeared to be three times more prevalent in the male than in the female. It was, however, a milder form than was found in Burma or China. In the face of untold difficulties—financial problems, shortage of technical staff, inadequacy of equipment, and numerous other encumbrances—a handful of men lived up to the finest traditions of the profession.

Visiting that colony, one could not help being impressed by the cheerfulness and high morale of the patients. Most of them were poor and paid nothing, but there were a small number of private patients who rented a one-room "cottage" at a nominal charge of 7 rupees a month. Even the worst cripples were surprisingly happy. One woman, who was permanently confined to her bed, took great delight in showing us how she could tie a spoon firmly to the stump of her forearm with the aid of her teeth. An old man who had lost both feet was entirely overcome with emotion when he told us how his hands had been useless and rigid, and now he could use them normally. Actually, he had a wide range of movement, though there was much arthritis and also hypothermia wasting. The gratitude of these people was most moving; the medical staff were practically worshipped. Those who could get about—and that included the vast majority of them—would render what assistance they could. Lectures were given to train them in the elements of hygiene and nursing so that they could help each other. There were classes on carpentry and needlework for the younger people, while nearly all of them were able to give a hand on the farm. The Settlement had its own herd of cattle, kept in first-rate condition, and, apart from the actual milking, nearly all the work was done by the inmates. Here was an active, self-supporting community, which was, in its pathetic isolation, an outstanding medical achievement.

CARE OF THE CHRONIC SICK AND OF THE AGED

We print below a summary of an address given to the Parliamentary Medical Group recently by Lord AMULREE, M.D., and Dr. E. L. STURDEE.

THE CHRONIC SICK

The first thing to remember about the chronic sick is that they are by no means all of them very old people. Figures from the county hospitals and institutions in Surrey show that in January, 1943, 29% of the chronic sick were under 65 years and 10.5% under 45. Among the latter may be cardiac cases, arthritis cases, and patients with conditions such as undiagnosed pernicious anaemia or "nervous" conditions.

On the other hand, perhaps 25% of the chronic sick are patients with arthritis or hemiplegias, a larger number of whom may be improved to the extent that they are no longer bed-ridden and may be able to go to their homes. It is therefore desirable that a hospital in which there are patients of this kind has attached to it a specialist in physical medicine and facilities for physiotherapy. Some people hold the view that each general hospital should have a proportion of chronic wards and also small annexes for various types of long-stay patients. Remembering that the elderly among the chronic sick fade imperceptibly into different grades of acute, chronic, infirm, and those requiring little more than skilled nursing oversight, provision for all such grades should be included in a hospital service, though not necessarily on the site of the hospital itself. In 1944 Sir Alexander Macgregor, reporting to the Glasgow Corporation, followed the same argument to some extent. He stated that patients all require a preliminary period of investigation and treatment, before being judged incapable of benefiting by further treatment and that even then patients should still have skilled medical attention available. He therefore considered that the problem of the chronic sick was closely related to that of provision for old persons generally.

Sir Alexander Macgregor also suggested that 10 to 20% of the total beds of general hospitals should be allotted to chronic sick, the difference in the number presumably depending on the type of hospital because "the policy of selection of patients has now reached a stage where the efficiency of the Corporation hospitals is seriously imperilled." His reason for saying this is the present-day tendency of giving priority to acute patients and leaving the others to shift for themselves. He recognizes that it is often a question of housing conditions, because there is a difficulty in looking after long-term illnesses in small houses, and help, either domestic or nursing, cannot always be obtained. For this reason it seems that the provision of some sort of accommodation for old persons who are not entirely capable of looking after themselves will have to be undertaken, and in providing this there is a medical responsibility which must not be overlooked. Proper classification of patients and accurate diagnosis are essential, which means that the expert diagnosis and treatment obtainable in a general hospital must be available for chronic cases and aged, sick, and infirm persons. Dr. Bluestone, superintendent of the Montefiore Hospital in New York, goes further than this and arranges for periodical consultations on long-stay cases, in which specialist advice is again sought in order to decide whether everything possible is being done.

Many of the patients who are kept out of hospital because they seem likely to stay a long time might, if admitted earlier, receive treatment which would prevent their remaining in hospital. General practitioners should, therefore, be encouraged to obtain skilled advice and treatment for patients with conditions such as arthritis or hemiplegias as soon as possible so as to avoid contractures. Sometimes patients are admitted to chronic wards who should be in acute wards, at any rate for a time, which shows the disadvantage of having so-called chronic sick in hospitals of their own instead of allowing them to participate in a general hospital service. It therefore follows that the diagnosis and treatment of the chronic sick should be looked upon as part of the duties of the more experienced medical staff.

An attempt should be made with all infirm patients to house together persons who are likely to mix well, but there will

always be patients who are likely to upset others and will need special discipline. For long-stay patients small units with a "homely" atmosphere are necessary, and everything should be done to remove the institutional atmosphere.

Not only is the problem of the treatment of the chronic sick not being met, but most people do not realize that there is a problem.

CARE OF THE AGED

This is a problem which is increasing* because of the ageing of the population, and the housing and other domestic difficulties which make the care at home of elderly persons more difficult. It is also no longer confined to one class of the community. At a hospital recently a retired colonel had to be admitted who normally should not have taken up a bed but that his wife had no domestic help and was unable to get anyone to help to look after her husband, who was suffering from paralysis agitans. In Coventry people of means have been admitted into a hostel run by the Public Assistance Authority because their relatives are unable to look after them. They are not hospital cases and they are paying the full cost of their keep, and in past years would probably have lived at home with a companion. The figures for deaths from accidents during 1945, which the coroner for North London has kindly supplied, show how large a proportion of fatal accidents occur among old people living alone or in conditions where such slight disabilities as they have are not properly looked after.

The solution of this problem is not entirely one of housing because, although those for whom accommodation is required are more or less healthy, they often suffer from some slight disability which may itself get worse or may lead to an accident unless they have care and attention. Others of them are able to look after themselves to a great extent but cannot undertake the whole of the domestic duties required if they live in their own homes without help. Death often occurs from the neglect of a small accident because, if there is no one to look after such people when they are well, still less is there anyone available when they are incapacitated.

Type of Accommodation Required

The easiest and sometimes the best type of accommodation for old people is the *hostel*, which should be run on the lines somewhat of a boarding house or private hotel. Every effort should be made to prevent the hostel becoming like an institution, and rules and regulations should be as few as possible. Attention must be paid to the special requirements of old people, such as the avoidance of slippery floors, of chairs which are not easy to get out of, and of unexpected steps in passage ways which are badly lighted. Arrangements also have to be made for old people to sleep at various times of the day, and as many of them prefer to sleep in their bedrooms the provision of a blanket or something of that kind for use in the afternoon is desirable. Lighting over the beds is a matter that requires attention because old people often like to read or knit in bed. The rooms in the hostels should be of a varying type. There should be some single rooms because it is a mistake to believe that people who are forced to live in communities need no privacy during the whole 24 hours. On the other hand, many people, especially the very old, feel frightened at night and like to feel there is someone else in the room. It is therefore desirable to have rooms which will take two, three, or four beds. More than this is inclined to look like an institution or a hospital ward. Mrs. A. V. Hill has made what seems to be a successful experiment in one of her hostels of having rooms for four persons which are divided up so that each person uses a part of the room as his own where he can keep his own property and where he can do as he likes without interference from the other people sharing the room. The rooms are, to all intents and purposes, bed-sitting rooms, and the inhabitants may have their meals and spend most of the day there. There might be an advantage in having cubicles or at least curtains in a room of this type. In the Surrey County Council's hostel at Farnham the single rooms are much

* In 1900 there were 1,750,000 people over 65 years of age in Great Britain. By 1937 this figure had increased to over 3,750,000; by 1951 it is expected to be 5,500,000—that will be 11% of the total population. (Dudley Committee's reports on the Design of Dwellings; H.M. Stationery Office, 1944.)

coveted and there is generally a waiting list for them. They tend there to be used by some of the older inhabitants who have shown that they appreciate living in the home.

Cottage Homes

Some authorities, both voluntary and public, have found that small houses are appreciated. It is often said from the experience of the Poor Law that old married couples show no desire to live together. But this is probably because when such an opportunity has arisen the couple has already lived some time in the institution and each has become accustomed to a new mode of life. Old people, like children, do not like changes, but where small houses or flats are provided in the first instance they are very popular.

An example of accommodation of this type provided by a local authority is in the Crookston Homes belonging to Glasgow Public Assistance Committee. These homes consist of small cottages, some for married couples and others for single persons, which have been erected on land adjoining the Crookston Public Assistance Institution. The cottages are built in blocks containing either eight cottages for married couples or 16 for single persons. Each cottage has a living-room with a bedroom opening out of it, a small kitchen with an electric cooker, and a bathroom. In the sitting-room there is a coal fire, but there is also a thermostatically controlled electric panel in the bedroom, and, as there is only a curtain between the bedroom and the sitting-room, the temperature of the whole cottage is the same. The residents are supplied with free coal, light, wireless, and full rations as they are all eligible to receive public assistance. They can cook their breakfast, tea, and supper in their own kitchen, but they are supposed to have their midday meal in the common dining-room. This is partly to ensure that each person has at least one proper meal a day and partly as a means of finding out if any of the inhabitants is sick. The kitchens are fully furnished and cutlery and china are provided. The staff consists of one trained and one assistant nurse with about six domestics. A doctor in the neighbourhood visits daily and is available on call. The matron of the Public Assistance Institution is also able to supervise the cottages. It is proposed eventually to house about 250 persons in these cottages. Each block of cottages will have a common dayroom. A large assembly hall, which has been used for an emergency hospital during the war, will be used for the midday meal. These cottages are expensive, being about 55s. a week per person, or 27s. a week if the cost of maintenance and buildings and repayment of loans is excluded, but they seem to serve their purpose. There are very few rules and the inhabitants can go out as they like and spend the night with relatives.

An example of cottage homes supplied by a voluntary association is the Bethany Homestead, Northampton. These homes were started in 1926 as a charitable venture by the Congregationalists and Baptists of Northampton. Since then a few cottages have been built for the Wesleys, and there is said to be a project to build a block for the Church of England. The Homestead consists of two-room cottages for healthy old couples. No rent is paid, but the occupant pays for gas, water, and food. They live their own life but are expected to be in their cottages by 10.30 p.m. On the estate there are also 18 rest-rooms where are housed people who are not quite fit enough to look after themselves entirely, and there is also a so-called nursing home which consists of three four-bedded wards, one four-bedded ward, and three single-bed wards. The resident nurses in the nursing home, and the staff consists of the matron, who is a State-registered nurse, and two or sometimes three assistant nurses, with about 15 unskilled persons to help. There are also a housekeeper and a domestic staff of six. In the cottages used by the healthy old couples there is, over the bed in each cottage, a bell which connects with the nursing home in case of sudden illness. The inhabitants of the cottages are usually looked after by their own doctor, but there is a local doctor on call in an emergency. The inhabitants of the rest-rooms have a certain amount of domestic help and take their midday meal in the common dining-room, but the furniture in their rooms is usually their own, except for the bed, which is supplied by the Association.

It has been suggested by many people that homes, of whatever kind, limited entirely to old people are not satisfactory, and Dr. Banks mentions in his report in the *Bulletin of the Ministry of Health* for June, 1945, that there is much to be said for the development of the cottage estate such as has been set up in Amsterdam. There are people of all ages on the estate, but it is possible to make special arrangements to ensure that the aged and infirm in their own homes have such medical and nursing care as well as domestic assistance as is required. Curran and his fellow authors take the same view in the avoidance of segregation (*Lancet*, Feb. 2, 1946).

Whatever kind of accommodation is provided, whether in flats, in cottages, or in hostels, some selection of the inhabitants

must be made. In some hostels, both voluntary and public assistance, there are people with some disability such as a chronic cough or a habit of excessive snoring, who tend to make friends and agree to share a room, but, both at Glasgow and at Farnham, the inhabitants know that if they cause trouble to the rest of the community they are liable to find themselves in the "poor house." It must be recognized that there is always likely to be a certain proportion of persons who are impossible to fit in anywhere except under strict institutional discipline.

Staff for Homes and Hostels

It is difficult to be dogmatic about this because, as was found during the war with residential nurseries, a highly trained person without a sense of vocation may not be as successful as a person without academic training who is enthusiastic about the work. So far as inquiries have gone at present, one of the best matrons in charge of a hostel for old people is a State-registered nurse, but a woman councillor in East Ham who was voluntarily looking after a hostel for the aged seemed an excellent type for the work, although perhaps liable to take risks owing to her lack of knowledge. A member of the Friends' Relief Society, writing in the *Quarterly Review of the British Red Cross* for October, 1945, states that in most of the Friends' Hostels for the Aged they have had married couples as wardens, but they have found that there should be someone responsible for the health of the old people in each hostel, although this need not be a State-registered nurse. A knowledge of home nursing and ability to decide when a doctor is necessary are the chief requirements, and Mrs. A. V. Hill thinks that there is a future for the assistant nurse in old people's hostels. It is easy to add to the number of the staff in the interests of safety, but so much depends on the type of old person (healthy but feeble, infirm, lame, etc.) that it is difficult to lay down standards, especially as a few enthusiastic persons will probably achieve better results than a larger number working by the clock.

Even the best type of master and matron trained in the Poor Law service is likely to be unsuitable in homes and hostels of the kind desired because they tend involuntarily to give an institutional air to the place. Further investigation may result in a clearer idea of the amount and type of staff required in homes and hostels for the aged, but what is quite certain is that people doing this work must avoid anything that seems like interference with the inmates and must adopt a helpful and sympathetic attitude towards them.

Heating and Lighting

There is a good deal of difference of opinion about the heating of homes for old people, and personal preferences and the difficulty of obtaining additional heat at the present time unconsciously colour some people's views. In general terms, it seems advisable that roughly the same temperature should be maintained all over the home. In some hostels old people have been seen resting in the afternoon in their bedrooms with the clothes over their heads to keep out the cold. It should be possible to ventilate the rooms from time to time during the day without running the risk of the inhabitants becoming cold when they go into another room. Central heating of a hostel prevents the crowding of the inhabitants round the one fire with the consequent institutional atmosphere which this produces. As old people often cannot see very well, the question of lighting is important. Bracket lights in common-rooms as well as a central lamp are necessary, and, as old people spend a good deal of time in their bedrooms, it is essential to have a light over the bed so that they can read or knit. Care must also be taken that the passages are well lighted, especially at danger points, such as occasional steps.

INTERIM CONCLUSIONS

Some members of the medical staff of the Ministry of Health have been studying the problem of the aged and the long-term sick patient for some time, but have only touched the fringe of it, because the ramifications are so many and because the subject is comparatively new and a number of associations and individuals are trying out different methods. This is satisfactory because in process of time ideas on the subject will become more defined. It is hoped shortly to visit homes for people of higher incomes, and this may modify some of the statements above.

One thing that seems certain is that there are at the present time four classes of patient filling hospital beds unnecessarily. First, patients with diseases which have become chronic and difficult to treat because they have not been placed under skilled treatment soon enough. Secondly, patients who have a disability but are taken into a hospital bed only because their friends are unable to look after them. Thirdly, patients who are suffering from an illness which could have been prevented

(for example, the result of an accident) if there had been someone at hand. Fourthly, patients who have been admitted with so-called chronic diseases which, under treatment, have improved so that the patients could return home but that they have nowhere to go.

In some hospitals there are, unfortunately, patients who have been allowed to remain in bed for months or years without proper classification or treatment, but it is to be hoped that these will cease to be found in the new hospital services. If satisfactory accommodation can be made either under the Housing Acts † or in other ways, for all types of people of the later age periods—that is to say, the apparently healthy, the slightly feeble, the infirm—many people now spending long months and years in hospital may be kept about, able to lead interesting and often useful lives until near the time of their deaths.

SCOTTISH STATISTICAL RESEARCH BUREAU

Following discussions which have taken place between the four Scottish Universities and the Faculty of Actuaries, a Scottish Statistical Research Bureau has been set up to bring together those who have statistical material which requires investigation and analysis, and those who have the experience to deal with the subject statistically.

It is known that valuable material is constantly being uncovered in many spheres of activity, but very often no attempt is made to bring out the facts which an investigation of such data might reveal, because the necessary time, labour, and statistical knowledge are not readily available. It is hoped that the new Bureau will close this gap. For example, a doctor who has collected data relating to a certain disease may be put in touch with an actuary who, as a practical statistician, will collaborate with him in getting at the facts behind the rough data. Larger investigations will also be undertaken, and it is intended that the Bureau, with its practical facilities, will act as a kind of clearing house. It should thus be the means of bringing to fruition research in the medical field and other fields which might not otherwise be carried out and the benefit of such research therefore lost to the community. During the war the practical benefits of statistical research were abundantly proved, whether the research applied to weapons of war, to industry, or to disease and sickness at home or in the jungle. What has been successfully applied during war could usefully be applied in peace in greater measure than has been the case in the past.

In its initial stages the Bureau will act only on behalf of individuals or associations of individuals who approach it through the Scottish Universities or the Faculty of Actuaries, which bodies will be the original members. It is intended, however, that other organizations interested in statistical research, in any field whatsoever, may later become members.

The Bureau will function through a central committee representative of the members. The first chairman of the Central Committee is Mr J G Kyd, Registrar General for Scotland, who is president of the Faculty of Actuaries. The secretary is Mr E Waugh, Faculty of Actuaries, 23, St. Andrew Square, Edinburgh.

† A housing association is defined in the Housing Acts. Such an association does not trade for profit but can construct, improve, or manage houses for the working classes. A local authority may, with the approval of the Minister, make arrangements with the housing association to help it in its objects.

German and Austrian children are to benefit from the latest relief plans of the Swedish Red Cross and the Save the Children Society, which have the support of the Swedish Government Committee for International Relief. Plans for Germany include feeding centres in Hamburg and the Ruhr, and probably also in Berlin, distribution of clothes, and medical assistance from Swedish doctors and nurses; those for Austria, daily meals for 10 000 Viennese children between the ages of 3 and 6 years, and distribution of clothing. The relief generally is to be given in all four occupation zones. Other news of Sweden's generosity is that Leningrad has received a second gift from the Swedish Government Committee for International Relief, this time of equipment for nine hospitals. The first gift, a year ago, was chiefly of medicines and vitamin preparations.

Reports of Societies

POSTMATURITY

At a meeting of the Section of Obstetrics of the Royal Society of Medicine on March 15, with Prof F J Browne in the chair, Mr A J WRIGLEY read a paper on the problems of postmaturity. He said that he had felt considerable dissatisfaction with the meaning of the word the diagnosis and management of the condition, and the lack of teaching on the subject. Many of our difficulties were self made, in that we acted on the assumption that if any pregnancy continued over the calculated date for its termination the foetus would become so large as to give rise to difficulty in delivery. That this was not the case had long been recognized. Almost half the babies of 9 lb (4.0 kg) and over born at St. Thomas's Hospital in 1945 had been delivered before the calculated date. Another series of cases showed how often a small baby was born after the expected date. Some textbooks stated that prolonged pregnancy did not necessarily result in a large child, while others ignored the subject or stated that the child was always above the average weight and length. Textbooks were also contradictory on the diagnosis of postmaturity. The majority of authors had written on the assumption that postmaturity was synonymous with excessive development of the foetus. Radiography was not much help in diagnosis. The appearance of ossific centres varied considerably and was of little value in assessing the maturity of the foetus. Many writers gave no advice on the management of women who had passed the expected date of confinement, some advised induction when the foetus was postmature but did not indicate when that state was reached, while others avoided interference. Weekly examination and induction were advised when the child was large and labour overdue. Estimation of the height of the fundus would never help, especially in the last weeks of pregnancy. Girth measurement varied in different women and did not greatly increase when the foetus was postmature, because there was no corresponding increase in the amount of liquor amni. The following, Mr Wrigley said, were additional physical signs of postmaturity: (1) when the foetus was truly postmature it was large, its weight being well above 7 lb (3.1 kg), this could be appreciated by repeated clinical examinations; (2) Concurrent with the increase in size was increase in strength and tone, which resulted in the whole foetus becoming more rigid, this rigidity could be recognized on clinical examination; (3) The amount of liquor did not appear to increase in the last weeks of pregnancy, and therefore as pregnancy advanced the foetus became more easy to palpate. Thus there might be a large rigid foetus easily felt in a uterus that contained little liquor, perhaps so little that the uterine wall might be thought to outline the foetal position and some of its limbs. These signs would be observed with reasonable certainty only if the doctor had watched the patient at regular intervals throughout the pregnancy and at frequent intervals in the later weeks. The amount of liquor varied in different women, but in all women there should be a relative, and as full time was reached a noticeable, apparent decrease in amount.

Mr Wrigley held that ideas on pregnancy and its termination needed revision. The "expected date" could only be approximate and it would probably never be possible at any time during the pregnancy to make a more accurate forecast. Three variations might occur: the expected date might come and go and labour start some days or weeks later with the delivery of a large postmature baby, or with the delivery of a normal-sized baby or even a small baby, or, at about the calculated date, a large oversized baby would be delivered that showed every characteristic attributed to postmaturity. An apt simile was that the pregnant uterus should be regarded as an oven, and just as there were slow ovens and quick ovens so would there be a variation in the time expected in the production of a cooked joint or a mature foetus. As a result of the differing advice in the textbooks doctors adopted one of two courses: either every woman who had passed the expected date received a medical induction or she was "left to Nature"; in the latter case the patient occasionally delivered herself of a large truly postmature baby,

perhaps with great difficulty and risk to both. There was no justification whatever for advising that a week or a fortnight should elapse after the expected date and then labour should be induced. If this course was adopted a number of women would go into labour later than they should be allowed to do, or, alternatively, the baby might not be mature. Another objection to routine induction was that it frequently led to repeated medical inductions. Apart from the physical upheaval of such proceedings, they were accompanied by a variable degree of anxiety which increased with each failure to bring on labour. It should be a rule that if there was justification for a medical induction there was justification for surgical induction. Doctors should continue to give patients estimated dates for their confinement, but should cease to believe and to teach that every woman would mature in the calculated 40 weeks. There should be no instructions to terminate pregnancy as a routine at the 40th week, 41st week, 42nd week, etc. Doctors should teach that by repeated observations at regular intervals there appeared a combination of physical signs that would indicate the course of action; that it might well be necessary to terminate pregnancy at the 38th week for a baby that was obviously large; and that in the absence of these physical signs interference was bad midwifery.

At the beginning of the meeting Dr. TITCOMB and Dr. DEANE showed a film of the movements of the human foetus, with a commentary by Sir Joseph Barcroft.

NUTRITION IN THE COLONIES

A conference of the Nutrition Society on "Nutrition in Colonial Territories" was held on March 2 at the London School of Hygiene and Tropical Medicine.

Col. WALTER ELLIOT, who took the chair, suggested that the present food restrictions in this country might at least make us more sympathetic about the nourishment of less highly civilized populations. The standards of nutrition in the Colonies varied greatly in different localities. Even in neighbouring territories, moreover, dietary habits and prejudices, such as religious bans on eating meat, might vitally affect the nutritional status and physical development. Striking evidence was obtained during the war to show that the nutrition of East African natives fell short of European standards. Troops recruited in Sierra Leone were very susceptible to tuberculosis, but after receiving European diets during the Burma campaign their resistance was much improved. The quantity of food was no less important than quality. A Chinese delegate to a League of Nations conference had once remarked that all Chinese were undernourished all the time. The key to better nutrition lay in improved agriculture, starting in the intelligent application of the principles of soil science.

Dr. B. S. PLATT displayed a map showing the disposition of the Colonies, which have a total of 66,000,000 inhabitants. The population of 21,000,000 was in Nigeria, while at the other end of the scale were the Falkland Islands with 2,000 and about 60,000 sheep. Density of population was greatest in Hong Kong, and least in Nyasaland. The nutritional problems to be faced, and the state of public health in general, varied greatly in different localities. Thus the neonatal mortality rate of 327 per 1,000 in Hong Kong was much higher than the rates in most other Colonies, and about ten times higher than in New Zealand, which had the world's lowest rate.

Malnutrition might be quantitative, resulting in varying degrees of starvation, or qualitative, in which case the characteristic deficiency diseases would ensue. The state of nutrition in populations might be assessed either by clinical examination of selected groups of people or by the detailed investigation of the quantity and quality of the food on which they subsisted. While under ideal conditions the same answer should be obtained by both methods the results in practice might sometimes be divergent. In this event suspicion should fall first on the dietary survey, which should be checked for any possible inaccuracies or unsuspected complicating factors. The first clinical signs of malnutrition were physically ill-defined. Mental symptoms were more easily recognized, and included apathy, and an attitude to authority commonly described as "bloody-mindedness." Remarkable improve-

ments in the mentality of African troops were found when they were transferred from native to European rations. Clinical evidence of malnutrition was obtained recently in Ceylon, when the war made it necessary to substitute wheat flour and coconut for part of the rice in the diet. As a result the death and neonatal mortality rates, and the incidence of sore mouth and of the skin condition known as "phrynodermia," were all substantially increased.

Dietary Surveys

In dietary surveys it was necessary to inquire how much of the various foodstuffs were eaten, and then to express the amounts in terms of the basic nutrients. Dr. PLATT displayed a long list in which he had tabulated data on hundreds of native foods. Differences in calorific intakes might be expected between communities accustomed to hard or light labour, and in practice the requirements of African natives were found to vary according to whether they lived on the shores of a lake, at the summit of a hill, or on the slopes of a hill in such a position that energy was constantly wasted in moving up and down. In assessing the amounts of food eaten, however, care must be taken to avoid a false impression caused by the time of the survey coinciding with a temporary shortage of supplies.

The traditional African ration of 1 lb. (454 g.) of maize and 1 1/2 lb. (227 g.) of beans daily left great scope for improvement, and an organized programme of action was necessary to improve the standard of nutrition and of living in general. The soil must be preserved and watered, and pests controlled. A correct balance must be struck between crops grown for home consumption and "cash" crops, grown for export. The food value of crops must be assessed in relation to the labour expended, and the present enormous waste of effort reduced by the introduction of modern methods and efficient farm implements. The cassava, from which tapioca was obtained, gave a high return in calories per man-hour spent in its cultivation. The storage of food, and its preservation by dehydration, must be arranged so as to provide for seasons when crops were scarce. Finally, there was a need for social progress. The native must be educated, and be given the incentive to work for a higher standard of living. Some system of apprenticeship was wanted to enable skilled trades to be passed on. Excessive fecundity should be prevented by birth control.

In carrying out this programme about 75% of the money available for improving nutrition in the Colonies would have to be spent on personnel. Field working parties were being organized, and were to consist of teams, each including a doctor, agronomist, administrator, and "nutritionist."

Dr. PLATT's paper was followed by a film showing the achievements of the Middle East Supply Centre during the war. The activities of this organization took place mainly in Egypt. The problems of irrigation, soil preservation, afforestation, locust control, and the breeding and insurance of livestock were all clearly illustrated. In addition it was shown that the fight against starvation and economic collapse was made difficult by the human element, since Arab farmers were persuaded by enemy propaganda to conceal their stocks of much-needed grain.

Problems of Malnutrition

Dr. H. S. STANNUS spoke next on malnutrition in colonial territories. In his opinion unknown deficiency diseases greatly outnumbered those already known. In the early stages of malnutrition, before the tissues sustained obvious injury, functional abnormalities occurred which were difficult to assess but which were associated with increased liability to fatigue, irritability, apathy, depression, giddiness, loss of tone, an neurasthenia. Clinical observations, laboratory investigations and dietary surveys all helped in the diagnosis of malnutrition. In clinical examinations grave doubts had recently been thrown on corneal vascularization as a sign of riboflavin deficiency and on keratitis pilaris as a sign of vitamin A deficiency. Moreover, it was grossly incorrect to attribute pellagra simply to deficiency of nicotinic acid. Good evidence had been obtained, however, associating macrocytic anaemia with deficiency of folic acid. The condition of reticulobulbar neuritis and the so-called infantile pellagra seem to be of nutritional origin, but had not yet been ascribed to deficiency

of specific nutrients. Laboratory methods of investigation had the disadvantage that heavy apparatus and fittings were needed, and they were therefore of little use in the field. In dietary surveys it must be remembered that the staple articles of diet might be supplemented by many seemingly small seasonal extras varying from wild honey to caterpillars, flies, and grasshoppers, which might have considerable nutritional importance. Diets in gaols might be supplemented by food brought in by friends of the prisoners.

The human subject could sustain life on widely different diet patterns. While the Eskimo ate nothing but flesh, and the Oriental coolie nothing but rice the prejudice for any particular diet might be very strong. In the Bengal famine some Indians when offered wheat instead of rice, preferred to die of starvation. The individual seemed capable of subsisting at different planes of activity, and after a period of undernourishment the metabolism becomes adjusted so that a new state of equilibrium might be reached at a reduced body weight and with curtailed physical activity. Dr STANNUS expressed misgivings as to how far an attempt at European standards of diet and civilization would improve the lot of the African tribes. He predicted that the disuse of native customs would be attended by over population, continued malnutrition and a high incidence of syphilis.

General Discussion

Dr J G REED said that valuable information had been collected in prisoner-of-war camps in Hong Kong and Singapore, which should be compared with similar data from British, American, Dutch, and Australian sources. One important generalization which had been reached was that mal nutritional disease was not clear-cut and constant. While syndromes such as that characterized by retrobulbar optic neuritis were extremely widespread in many camps, the evidences of malnutrition overlapped and interlinked in a complex pattern. Food yeast, local fermentation products, and easily grown green vegetables had proved valuable as supplements.

Dr N C WRIGHT dealt with the relation of animal husbandry to human nutritional needs. During the earlier stages of Colonial agricultural development emphasis was invariably placed on plant husbandry, and except in predominantly pastoral areas the parallel need for the development of livestock husbandry was overlooked. In the 1939 report of the Colonial Nutrition Committee the most striking finding was the almost complete absence of milk, and indeed all animal products, from most Colonial dietaries. Although this lack did not apply to natives of East Africa, Northern Nigeria, and the Middle East, animal husbandry even in these great pastoral areas was very inefficient. The animals suffered from overcrowding, drought, disease, and gross undernourishment at certain seasons of the year. The necessity for using oxen for draught purposes reduced the milk yield, but with improved breeding and nutrition the native strains could be much improved. In the predominantly settled areas, comprising mainly the territories of the wet tropical belt, the animal population was disproportionately low in relation to the nutritional requirements of the human population. In the whole field of animal nutrition new ideas must be probed, new methods investigated, and new projects boldly planned and executed. Dr W R WOOLDRIDGE reminded the Conference that the Colonial Veterinary Service had already done much useful work on the control of epizootic diseases such as rinderpest.

Miss AUDREY I RICHARDS discussed sociological factors in relation to Colonial nutrition. The Colonial Social Service Research Council could help in finding out what changes in the social habits would be necessitated if the proposed improvements in dietary standards were to be obtained. Mr A J WAKEFIELD congratulated Dr Platt on the good progress of his campaign for improved nutrition in the Colonies, and promised agricultural support. He indicated the plight of the West Indies, where concentration on a single export crop, such as sugar, had prevented the adequate production of home-grown foodstuffs for a dense and rapidly increasing population. Prof R FIRTH discussed the influence of social factors such as hospitality and religious prejudices, on the consumption of food. Sir JOSEPH BARCROFT, in philosophic vein, reflected that it had been the lot of most mankind to be undernourished from

time immemorial, and that any systematic attempt to improve the position might lead to larger populations, resulting only in an intensification of the state of chaos which civilization had already reached.

In summarizing the day's proceedings Col ELLIOT said that the conference had been fortunate in hearing first hand comments from several experts from overseas. While the film shown earlier in the meeting had emphasized the more romantic aspects of the struggle for improved nutrition, the real need was for day to day "plugging on the part of the administrators." It was essential that the desirability of "profit" crops should not lead either to the natives neglecting their own food requirements, or to an undue drain on their soil. Nitrogen in the form of meat or cattle cakes and phosphates in the form of bones should not continually be exported to temperate zones without provision for their replacement. A higher standard of living based on larger crops, could not be expected from an impoverished soil.

Correspondence

The Health Service Bill

SIR,—The medical profession, as we all realize, is now at a critical period in its history when far reaching decisions which will affect the course of medical practice for generations, must be taken. As one who is within a few years of the end of his career and who will be little affected personally by the National Health Service proposals, I am wondering whether the action taken during the last few months by the leaders of the profession is best calculated to ensure that the Bill, when it finally passes through Parliament, will produce a medical service which will provide to the patient a first-class medical service and will at the same time, enable the medical practitioner to work under conditions satisfying to him. Week by week in the *Journal* we see a spate of high-sounding words which baffle rather than instruct, and we seem, as a profession, to be in grave danger of scattering our energies in promulgating principles some of which stand very little chance of being accepted by the community at large or being sympathetically considered by Parliament.

Medical men have the reputation—not always deserved—of being poor business men, but there never was a time when the profession required more urgently the business instinct of knowing what is possible and what is not and concentrating on the possible. We have in front of us a Bill for the drastic reorganization of medical services promoted by an able Minister, with a large majority in Parliament, who conscientiously believes that his proposals are in the best interests of the country. He is well aware of the almost chaotic conditions under which the public health, hospitals, and medical services have been working for many years, how defective in many respects these services are, and how urgently drastic reforms are needed. Having all the facts of the previous proposals before him, he produces a Bill which, with all its faults, is a most courageous attempt to reduce to some kind of order the existing services. I have been associated with the negotiations in regard to the new medical service from the commencement, and as a result am convinced that no scheme could be produced which did not contain some anomalies so complicated have the services become during the course of the last fifty years. The Minister's scheme has its anomalies—notably the separation of clinic services, in some cases, from hospitals—but, as it seems to me, it is fundamentally a sound scheme which, if amended in some particulars, and if generously administered, would provide an efficient medical service for the community.

My criticism of the B.M.A.'s policy, so far as I know it, is that it seems to be dissipating its energies in a cloud of words instead of concentrating effectively on the one single point which affects so vitally the future of the profession. The only point of really vital importance to the profession, as it seems to me, is that of its freedom from official control. This point can be readily grasped by the layman, who is going to be the final arbiter on this question. Such control is to be imposed

in the Bill in two ways—by prohibition of the sale of practices and by the proposal to remunerate practitioners largely, but not entirely, on a salary basis. Admittedly the sale of practices in the past has not always produced satisfactory results in some areas, but the alternative of prohibition as a cure for a not very serious evil appears absurdly drastic, and the penal clause, involving fine and imprisonment, seems a new departure in English jurisprudence. If, however, the profession fails to secure the omission of this proposal from the Bill, doctors in the service will be appointed by the local Executive Council and their freedom of action, and even their freedom to practise the profession for which they have been so long and so expensively trained, will in the long run be grievously curtailed. The second point in regard to payment by way of salary is of equal importance. Even if remuneration is at first 50% salary and 50% capitation fee, this basis of payment can at any time, by regulation, be changed to 100% salary and 0% capitation fee. The power to make regulations, usually without an affirmative resolution of both Houses of Parliament, conferred in the present Bill and much other legislation gives to a Minister, and, of course, the Civil Service, great powers which may, or may not, be used wisely. This power could be used to reduce still further the freedom of the profession, of course in the interests of efficiency, in the future. Regulations are essential in connexion with a service of this kind, but, in view of their importance, it is to be hoped that the Association will attempt to procure an amendment of Clause 69 (2) of the Bill providing that all regulations shall be laid in draft before Parliament and approved by resolution of each House.

I am aware, of course, that the B.M.A. has the matters referred to above in mind. The purpose of this letter is to make a plea for simplification of procedure and for concentration on one or two vital points. If the Minister can be persuaded to accept the proposed amendments his scheme for the reorganization of medical services will not become thereby less efficient or more difficult to administer, and he will gain the sympathy and support of a free profession willing and anxious to co-operate in the provision of a first-class service.

The dropping of proposals for the prohibition of the sale of practices and for any payment by way of salary will admittedly be in the interests of the medical profession, though it will not adversely affect, and might improve, the efficiency of the service. Let us admit this frankly instead of pretending that all we do is in the interests of our patients. The medical profession has, in the past, deserved well of the community. In return we would now ask the community to allow us to retain a similar measure of freedom to that still accorded to other professions.—I am, etc.,

The University, Liverpool.

W. M. FRAZER.

SIR,—The many letters and the divergent opinions expressed in the Health Service Bill in the *Journal* of April 6 seem to confirm the opinion that I have formed, after many years' experience with medical committees—that the doctor is a poor politician because he sees many sides to every question and finds it difficult to make up his mind; sometimes he requires a long time to come to a conclusion, and may even wish to reconsider the position when new evidence is produced.

I trust that the B.M.A. is going to produce a scheme of its own as an alternative to Government suggestions. I am well aware that attempts have been made for many years to persuade the Government to accept a scheme, but I do not know that the exact details of such a scheme have been published. I trust that the leaders of the profession in the Royal Colleges and the Association will lead, and will not wait to see which way the tail of the profession is going to wag.

There are some facts that are perfectly clear. This Bill affords powers to the Minister of Health which will enable him to dictate to the individual doctor or hospital; indeed, he has already shown his hand in his attitude to the (so-called) Negotiating Committee, for no negotiations of any kind have taken place: "Ministers do not negotiate." This Bill is a Socialistic political move aimed at ensuring a sound actuarial background for the national insurance scheme; it will tighten up certification, make every practitioner who signs certificates a State-paid, State-controlled servant, and render him liable to inspection. The Bill is not a constructive measure for the

improvement of national health. There is no offer of adequate numbers of hospital beds; there is no hope of the immediate production of new health centres; and without a considerable increase in the numbers of doctors, dentists, and nurses the scheme is quite unworkable in 1948.

To call the scheme a "comprehensive health scheme for all" is most misleading. If there were five times as many dental surgeons, all working, they could not do the work necessary to provide a comprehensive dental scheme for the population of this country, and to make this Bill a practical measure the number of general practitioners must be at least doubled, and the number of consultants in all branches of medicine, surgery, obstetrics and gynaecology at least trebled. When a consultant's opinion costs nothing the public will demand that opinion on every possible occasion, and the practitioner will, naturally, support them. A good doctor is always glad to receive confirmation of his opinion and assistance in his management. Is Mrs. William Jones in Wales to be debarred from the benefit of the opinion of Sir Thomas Smith of Harley Street when she is ill? And if she is so debarred, why?

But already there are variations in the interpretation between the Bill itself and the Summary, as pointed out by Dr. N. Cridland. Which are we to believe? No doubt the Minister himself will ultimately decide what he means. There are some optimists in the profession, such as Dr. J. L. Henry, who suggests that we must not organize any resistance, even if we dislike the Bill, and should use our not inconsiderable influence in Parliament to bring about modification. I can only suppose that Dr. Henry has not had time to read or listen to reports on Parliamentary procedure. This Government has a large majority and they are not accepting any single modification or amendment to any of their proposals. Their legislation is forced through whatever the opposition may be.

Dr. M. J. Bradlaw's letter appears most important. The Minister is going to offer compensation for loss of practice on the death or retirement of a practitioner. The basis of such compensation has not yet been discussed, but the compensation will be in the form of Government bonds carrying 2½% interest; the net return from these will be about 1½%. But there are even more serious aspects of this suggestion. I suppose every doctor enters his profession with the general idea of earning a living, and after this the various doctors are differentiated by the other factors which govern their practice. The able practitioner is ambitious to establish a reputation to do his patients good; to widen his practice; to obtain greater skill, knowledge, and senior qualifications; and in the past his interest in his practice has been such that he has taken the greatest care in securing a suitable partner or successor (perhaps a son) who will continue the tradition of the practice and pride in personal achievement.

All ambition to build up a good practice will be killed under a nationalization scheme. If the Socialist Government has started in another way and had said: "We wish to improve the medical service of the country; we wish to increase the number of doctors and dentists, nurses and midwives; we want to make every doctor more efficient by providing better education, more secretarial help, and more domestic staff; health centres with every convenience for high-class practice; extra hospital beds so that all the sick may be treated under the best conditions; and we shall be glad to have suggestions from the medical profession for the co-ordination of such services, then the medical profession would have been keen to co-operate. At present they seem to be divided between those who view the Bill with apprehension and yet apathy because they do not know where to turn; and those who hope, like myself, that we are not going to see our profession and our hospitals nationalized by a Socialist dictatorship.—I am, etc.,

Birmingham.

K. DOUGLAS WILKINSON.

SIR,—How stimulating it is to read a letter like that of Dr. William Gray (April 6, p. 542) after the wails and lamentations about the Bill which usually appear in your pages! I am in entire agreement with everything he says. I, too, have thought, since my student days twenty years ago, that the question of money in the doctor-patient relationship should be entirely eliminated. I thought then, and still think, that an ill person is in need of the best help available, and that the question of

payment for this help ought not to arise at all. The theory advanced by the B.M.A. and so many members of our profession that a salaried doctor would not care for his patients to the very best of his ability is an insulting one. Surely any doctor who would be influenced by money received is not worthy of being a doctor at all.

Perhaps Dr Gray has not perused the correspondence about the Bill in the *Journal* as carefully as I have. If he has he must surely have learnt with amazement how despised the doctors in the public health service are by the rest of the profession. Because we receive a salary and do not collect fees from our patients we presumably care nothing for the welfare of our patients and have no loyalty towards them but only towards our employers. I admit that these doctors so indignant about their practices being taken away and a salaried service substituted, might pity the public health officers for having so little business acumen as to be content with a bare living wage rather than piling up a bank balance, but I think it time that someone protested against the idea that we do not consider our patients or do all we can to help them—I am, etc.

WINIFRED M. COPPARD
Asst. C.W.O.

Dunmow, Essex

SIR.—At the B.M.A. meeting in Birmingham on April 7 I voiced my fears that we would fail to present a solid united front in our fight for the rights of the individual. I suggested that the B.M.A. should become a trade union, this being the most efficient way to fight the dictatorship of Whitehall. In reply Dr Dain explained that the Government would not license a new medical trade union.

I am ever mindful of the debacle of 1911 and feel that the majority of medical men would be more content to know for certain that there would be no backsliding and no blacklegs and that we would all stand shoulder to shoulder in our refusal to co-operate with the Government until the seven essential Principles laid down by the B.M.A. are incorporated into the National Health Service Bill. Let us recognize that we are fighting for the liberty of the individual and the safeguarding of the rights of the public as well as our own profession. We are the first body of people to be attacked, but, make no mistake, if we go back on our Principles and refuse to fight we shall not be the last. I therefore suggest that local meetings be called immediately, and all medical men requested to sign a pledge that they will refuse co-operation until the Government amends the Bill to incorporate our Principles. We shall then know where we all stand, and Mr Bevan (who now relies upon splitting us) will know also. Without our co-operation the Bill, even if passed into law, is moribund.

I further suggest that the colleges and the universities be approached and requested to postpone all further final examinations until Mr Bevan listens to reason. This step, combined with a huge publicity campaign, will make the Minister of Health realize that the medical profession and the British public will not submit to dictatorship whether it be Nazi or Socialist.

The time to act is now and not when the Bill is passed into law. So let us go forward shoulder to shoulder, secure in the knowledge that we fight not only for the principles of a great and honoured profession but for the elementary rights of the whole British democracy—I am, etc.

Birmingham

MARK J. BRADLAW

SIR.—G.P.s are confronted with a difficult situation in being asked to formulate an opinion on the new N.H.S. Bill in the absence of details about remuneration. Without that information it is impossible to determine whether the average doctor will be reasonably contented in the new service and, in consequence, the public satisfied by the service. Although G.P.s would embark on the scheme with the best intentions, the present number would possibly be unable to cope happily with the greatly increased number of patients seeking their services. If remuneration for the increased work is considerably less than his present income what attitude is any doctor likely to adopt? It would be difficult for him not to view many of his patients' attendances as unnecessary, and the changed attitude of doctor to patient would inevitably result in an unsatisfactory service. The majority of doctors cannot divorce conscientious service

to the public from financial considerations, however good their intention to do so.

Basic salaries and capitation fees are discussed, but in the profession there is no unanimous desire for either or both. An alternative has not been put forward which would prevent a doctor from feeling that he was being imposed on and the patient from getting the impression (rightly or wrongly) that his calls on the doctor were unwelcome. Would the attitude of the doctor to his patients be less disturbed and his patients receive greater care and attention if the financial reward were to vary with the amount of work done and not depend only on the number of persons on his list? Would not a small capitation fee plus a scheme of payment on lines similar to those of the National Deposit Friendly Society and the Army civilian practitioner bills make for a more satisfactory service? Each patient in the National Health Service will probably have a medical record envelope as used at present in the N.H.I., and it could contain cards for the purpose of claiming fees (not from the patient). Some method of preventing dishonest claims could surely be devised.

It is generally believed that the National Health Service Bill will be passed but it can fulfil its aims only with the full co-operation of G.P.s. Satisfactory remuneration, based on raising every patient to the status of private patient, would ensure successful operation of the service, and the objects for which the Bill is introduced could be achieved. But in its present incomplete form one cannot possibly decide in favour of the Bill—I am, etc.

Creswell, Derbyshire

S. H. EVANS

SIR.—Among the many letters published in the *Journal* on the subject of the new Health Service Bill there have been few on two matters which concern general practitioners most intimately. These two are compensation and remuneration.

The offer of compensation is the most juicy of the baits so far thrown to us and as such is the one most likely to lead us into error. It is said to be made in order to compensate us for the loss of the capital value of our practices. We may ask, Why should there be any loss? There can only be loss of that capital value if we are denied the right to buy or sell our practices. There will be no loss if we retain that right. If, therefore, we accept compensation in any shape or form we have at once thrown away not only the capital value of our practices but also our independence, and we have committed ourselves irrevocably to accept the terms of service offered us from time to time, whether we like them or not. From past experience we can be certain that these terms will not be generous.

Why, then, should we so easily allow ourselves to be bamboozled into suffering this unnecessary loss of capital value? Why should we not avoid it by insisting on our own right, in the same way as any other law-abiding citizen of this country, to buy or sell the goodwill of our practices, not only to whomsoever we choose but at whatever time we choose, whether we take part in the new service or not? The trap for the surrender of our liberty is well laid. Let us not walk into it so blithely. Let us tell Mr Bevan in no uncertain terms, "Our practices are not for sale. We do not want compensation for loss of capital value, for there need be none. We insist on the right to buy or sell our practices at all times. We will not be bought out and have a 'forced loan' imposed on us." This question of "compensation" thus becomes vital if we wish to retain any freedom from control and regimentation which, it is obvious, is the primary object of the present proposals.

Dependent on the right to buy or sell as set out above, is the point that we cannot accept a basic salary. Naturally we cannot buy or sell a salary. It follows that remuneration must be by way of capitation fee. Here again we must insist that the capitation fee should be adequate, guaranteed, and constant, no matter how many patients a doctor has on his list. There is no justification whatever for the penalty of expecting us to treat any particular patient for a smaller fee than that decided upon, simply because we happen to have been chosen as medical attendant by a certain number of other patients.

Incidentally, by refusing to accept "compensation" we would be saving the country the not insignificant sum of £66,000,000—I am, etc.

Newport, Mon.

C. N. COHEN

The Minister Listens

SIR,—Sir E. Graham-Little (March 30, p. 503) appears to be very annoyed at my letter (March 16, p. 411), but that is no reason why he should distort it beyond recognition in his reply. I did not say that 40,000,000 people were all "united," or that these same people were attempting to "coerce" anyone. I made no statement of the numbers who voted at the General Election, but sought to contrast the small number of some 50,000 doctors with the huge figure of some 40,000,000 people who are the prospective patients of those 50,000 doctors under a Bill for a more modernized, a more humane, and a more democratic system of treatment.

The Government of this country, during its term of office, is always recognized as representative of the people, and it is against the endorsed scheme of this representative Government for better health conditions for the nation as a whole that certain doctors are urging sabotage. The main excuses brought forward for this sabotage are objections to the small measure of direction which the scheme urges for the benefit of those who are badly placed for medical treatment; objections to the stoppage of buying and selling of the treatment of patients *en bloc*; objections to whole-time salaried service which, they claim, interferes with a doctor's freedom; objections to the rapid and immediate efforts to open large numbers of health centres which would improve the working facilities for doctors and others and whose efficiency could be further increased as experience of their working was collated; objections to the taking over of voluntary hospitals (many of which are out of date and lack sufficient funds), which pick and choose their patients and contrive to get most of the limelight although the ratio of beds in voluntary hospitals to those in municipal hospitals is of the order of 1 to 5 in the whole of the country; and objections generally to the harnessing of the profession as a more closely working team for the benefit of the country as a whole. In other words, the objections of these saboteurs are mainly from the narrow professional viewpoint.

It is true that they also claim much virtue in their anxiety about that somewhat ill-defined condition which they term the doctor-patient relationship, but is not this a considerable slur on their numerous colleagues who are working in whole-time salaried jobs up and down the country? Have they ever considered the nurse-patient relationship? Are nurses any worse nurses because their salary—a scandalously low one—is paid to them by a hospital board or by a local authority instead of being collected on a capitation system? And is it not possible that our patients, who, by the way, did vote at the election, have a very shrewd idea of what would benefit their own "health and happiness"? They know their doctors—at any rate they know the general practitioners who form the majority in any national health scheme for doctors—and they do not appear as a class to be worried about this doctor-patient relationship.

Sir Ernest's own assertion that the "vast majority" of our doctors sincerely believe that acceptance of the Government's proposals will worsen, rather than better, the nation's health and happiness is an astounding piece of wishful thinking for which he forgets to offer any evidence. Where are his "authentic figures" for this grotesque statement? Can it be that he finds them in the B.M.A. questionnaire or from that majority of the group of doctors who also sit in the House of Commons and disagree with his opinions?

Lastly, he must surely agree that the Labour Government is the representative Government of this nation of 40,000,000. For otherwise it follows that he, who received only 7,618 votes out of an electorate of some 24,000 and won his seat by the narrow majority of 149, is not the representative Member for the University of London. Which is unthinkable.—I am, etc.,

London, N 3.

P. G. S. DAVIS.

Paralytic Ileus

SIR,—If Mr. Rodney Smith (Feb. 16, p. 253) had read my letter (Feb. 2, p. 177) more carefully, he should have realized that I had no desire to belittle the value of "suction-drainage," my main wish being to point out its advantages—but also its limitations. The vast majority of surgeons in this country are "fully conscious" of the value of suction-drainage—and also

of its shortcomings. While very many good things have had origin in America, and I would not for a moment belittle the tremendous advances achieved by so many of their pioneers in the field of surgery, we must not lose our sense of proportion or our critical faculty. This is a mechanical age and America is a highly mechanized country. We must beware of the tendency to mechanize our patients. Fortunately this "Brave New World" of "R.U.R." has not yet arrived! The best surgeon is not necessarily the one whose patients positively bristle with gadgets, nor do patients hemmed in by such a barrage of machines necessarily do best.

I am well aware of the value of suction-drainage in operations on the oesophagus or cardio-oesophageal areas, where leakage is so prone to occur after anastomosis of stomach or jejunum to oesophagus. Very many surgeons, myself included, invariably use suction-drainage with operations on the stomach, duodenum, or small intestine, to prevent gastric or duodenal dilatation. Its value in the treatment of penetrating wounds of the intestines is quite beyond question, due to the greatly increased but incalculable risk of intra-peritoneal infection added to the other hazards. But when the fluid and/or flatus collect in and remain in the lower jejunum and ileum (as in true paralytic ileus) I do not believe that suction-drainage of the stomach, duodenum, or upper jejunum alone is the best form of treatment. In true paralytic ileus there is neither peristalsis to carry the tube down to the distended bowel nor reversed peristalsis to carry the fluid and/or flatus up to the tube. Otherwise ileostomy would not have failed so universally. Of course suction-drainage alone will succeed admirably with the lesser and more transient degrees of functional post-operative distension, or in cases of physical obstruction where there is active peristalsis. The distinction between slight transient distension and paralytic ileus is very difficult to define in the all-important early stages, for it seems to be mainly a matter of degree and duration. Absence of peristaltic sounds even for long periods is not enough. The normal abdomen is often quite silent for long intervals, as also is the distended abdomen, whether due to transient distension, paralytic ileus, or complete physical block. There will be noise only where there is movement, usually through a narrowed lumen as in partial physical obstruction.

I entirely agree with Mr. Rodney Smith that "the prevention of the vicious circle" is of paramount importance. Hence my advocacy of "eternal vigilance and prompt action" (Feb. 2, p. 177). But I am still firmly convinced that my scheme of active prevention is much more rapid and certain than suction-drainage alone. Perhaps I did not make it sufficiently clear that I always employ this latter method when there is any accessible fluid or flatus to be aspirated. But I have seen patients die from toxæmia because this method alone was persisted in, who could certainly have been saved by the early active treatment described. I stress the word "early," so as to avoid Mr. Smith's "vicious circle." But what evidence is there in favour of "a paresis of the intestinal muscle"? Could not the lesion be at the myoneural junction or in the parasympathetic system higher up? Might it not be due to deficient production of acetylcholine at parasympathetic nerve-endings, or its abnormal destruction by cholinesterase? Or might it not be due to central overaction of the sympathetic system inhibiting the parasympathetic? The condition is as full of possibilities as the abdomen is of fluid or flatus! Again, how do we know that in true paralytic ileus the muscle will "resume its function when it has recovered its tone," and that "this recovery is best facilitated by resting the gut as much as possible"? I maintain that such masterly inactivity (as regards effectively dealing with the dilated ileum) merely favours the development of Mr. Smith's "vicious circle," as well as prolonging the toxæmia. I have found that early treatment with prostigmin may initiate peristalsis alone without the need for an enema. So there does not appear to be a "paresis of the intestinal muscle," unless and until late in the "vicious circle," when the intestine has become hugely dilated, anoxic and devitalized, and will never contract again. I have not seen any patient "made worse by such treatment," unless it had been left till too late, when he was already moribund.

I must thank Mr. Rodney Smith for correcting a rather loose and careless use of words on my part in referring to "gastric suction with a Miller-Abbott tube." In a spirit of grateful-reciprocity might I point out a similar mental aberration on his part, when he states—"but the enormous volume of fluid withdrawn by suction does not mean any greater necessity for intravenous fluids, for stagnant fluid left in the dilated intestine is just as much lost from the general circulation as that withdrawn by suction." The "stagnant fluid" left in the dilated bowel, provided none of it has been taken by mouth, must all of necessity have been secreted by the bowel, and must cause a loss of fluid and chlorides from the body, whether these were sucked out of the bowel or not. Therefore they must be made good by intravenous saline. The daily urine output will indicate whether enough fluid is being administered intravenously. Estimation of urinary chlorides will indicate whether these are being replaced adequately. Chlorides will disappear early from urine unless adequately replaced intravenously. Urea will be retained in the

blood to an abnormally high level later on, to maintain a normal osmotic pressure, if the chloride and protein deficiency is allowed to progress. So it too, will tend to disappear from the urine, but only when the plasma proteins have already fallen.

Mr Smith calls neglect of physiological stimulation of the dilated bowel "physiological rest". Since the dilatation is due to some pathological cause I would suggest that physiological stimulation is the correct form of treatment. Can one call it "physiological rest" when the ileum and perhaps the lower jejunum are dilated with toxic and stagnant fluid left in it? As regards attempting "to coerce the gut into contracting while it is dilated and therefore at a great mechanical disadvantage" surely he has not forgotten that stretched muscle contracts more forcibly when stimulated than unstretched muscle, and the tone in muscle increases with stretching. That is provided it has not been neglected too long by "physiological rest" thus entering the "vicious circle". Eternal vigilance and prompt action are the answer.

With regard to Mr Michael Harmer's painful experience with prostigmin (Feb 16, p 254) I would suggest that in his case it was not necessary. As he had such severe peristalsis after the prostigmin he was suffering from post operative distension due to some physical intestinal obstruction and not true paralytic ileus. As regards the "small faecal object" passed as I have said before (Feb 2 p 177) the need for treatment should be gauged by the tension of the distended abdomen and the success of treatment is gauged not so much by the amount of faeces and flatus passed as by the increased softness of the abdomen afterwards.—I am, etc

Mount Vernon Hospital, Northwood

ALAN SHORTER

Treatment of Chest Wounds in Forward Areas

SIR,—It was with interest that I read the article on the treatment of chest wounds in forward areas by Major W. Michie, Capt. H. W. C. Baile, and Capt. J. Macpherson (March 30 p 482). The impression is given that tension pneumothorax will be relieved by the introduction into the pleural cavity of a wide-bore needle with a one way flow attachment. Admittedly this is sufficient treatment in most cases, but it does not always work. I remember seeing a man in an advanced surgical centre in Italy who was treated in this way. Air escaped continuously under high pressure from the affected side, but the displacement of the mediastinum continued, with all the associated symptoms, and he died. At necropsy a small shell splinter was found embedded in a wound on the costal surface of the lung, the bronchioles were laid open, and kept open, by the foreign body. The collapse of the lung had not closed the wound as expected.

Soon after this I encountered a similar case which showed no relief of symptoms by attempted reduction of the pressure in the chest. With the lesson of the previous case before me I opened the chest, and again found a small lung wound from which air was being discharged into the pleura—a piece of metal 1 cm by 1/2 cm lying there keeping it open. This was removed and the wound sutured, the patient making an un interrupted recovery. It is apparent therefore that thoracotomy is indicated in any chest wound complicated by tension pneumothorax which does not respond rapidly to the recognized treatment.—I am, etc

Newcastle upon-Tyne

JOHN SWINNEY

Smallpox in the Vaccinated

SIR—In your annotation on smallpox in the vaccinated (March 30) you quote the late Dr T. F. Ricketts. The common tendency is both to underestimate and to exaggerate the capacity of vaccination to protect against smallpox. As the proposal to repeal compulsory vaccination is now before Parliament and the country in the National Health Service Bill, the question of just what vaccination can or cannot do is of more than academic interest. May I therefore suggest that the tendency to underestimate referred to by Dr Ricketts relates to the effect of vaccination in protecting the individual while the tendency to exaggerate occurs in relation to the effect in protecting the community. In all the 34 years during which I was M.O.H. for Leicester I never had a single member of my staff in the health department the ambulance service, or the smallpox hospital contract smallpox, the only precaution taken to secure this satisfactory result being to ensure that all

were freshly vaccinated before going on smallpox duty. This proves what vaccination can do in protecting the individual.

But it is quite impracticable to protect a whole community in this way. Infant vaccination, as has been proved over and over again will not do it, while repeated revaccination, even if it were desirable, could never be enforced. I will go further and say that infant vaccination which is not followed by revaccination may even be worse than useless, because, as you rightly point out, smallpox in persons well vaccinated many years before is often so highly modified that it is very easily overlooked yet it may spread the disease broadcast in a highly virulent form.

For very many years infant vaccination in this country has been steadily declining, yet instead of the deaths from smallpox increasing they too have declined until they are now almost negligible. After all it is only the child population which is really protected by infant vaccination, and one of the lessons to be learnt from the experience of an unvaccinated town like Leicester is that, under modern conditions of combating the disease, smallpox is essentially a disease of adults.

The purport of this letter is to suggest that even though infant vaccination falls still more into disuse when compulsion is repealed—and personally I believe that it will do so—there is no serious reason to fear that smallpox mortality will increase.—I am, etc

C. KILLICK MILLARD

Leicester

M.O.H. for Leicester 1901-4

"Cord Round the Neck"

SIR,—While I agree with Mr Mortimer Reddington (Jan 19, p 109) that a cord around the neck of a foetus will never cause a stillbirth by compressing the trachea, yet I am not so sure that the progress of labour may not cause fatal compression of a cord which is wrapped round some part of the foetal anatomy.

Mr Reddington makes the point that the uterus, placenta, and cord all descend *pari passu* with the presenting part of the foetus so that the tension of the cord must remain constant throughout labour. Do they in fact do this? If a piece of elastic 6 in (15 cm) long, but stretched to 12 in (30 cm), is relaxed, one end being held in the same place, the loose end will move 6 in (15 cm) but the centre of the elastic only 3 in (7.5 cm). Similarly, if the fundus of the uterus were to move downwards the same distance as the presenting part, so too would the insertion of the cord only if the placenta were implanted on the fundus. If the insertion of the cord were halfway down the upper segment, then it would move only half the distance of the presenting part of the fundus. If it were somewhat tight at the beginning of labour it would be tighter still by the time the head had reached the perineum. If the cord were inserted battledore fashion at the lower edge of a placenta situated anywhere but on the fundus, then it would be further from the fundus and would descend proportionately less.

This is assuming that the fundus does, in fact, move downwards as the presenting part does, but it may not necessarily do so. The girth of the uterus is greater than the girth of the foetal head. As the head descends, the space which it leaves behind is at once filled up by liquor from above. The upper segment retracts this same volume, but the resulting decrease in the length and breadth of the uterus is very small and, be it noted, it is the breadth as well as the length which decreases. To make the matter clearer suppose a child's balloon were inflated and a piece of glass tubing 1/4 in. (0.63 cm) wide and containing a piston inserted into the mouth-piece. The piston could be blown many inches along the tubing before the deflation of the balloon became noticeable. If the piston were attached by a piece of loose string to the interior of the balloon this string would soon become tight. This is, of course, greatly exaggerating the mechanism of the foetal expulsion but the principle is the same so long as there is a fair amount of liquor.

Nor can one entirely neglect the movements of the shoulders. If the cord is entwined round one of them and tight at the beginning of labour rotation of the shoulder during labour may pull upon it and compress it. The movements of the shoulders, except those that occur after the birth of the head, are not given much

attention, but there can be little doubt that they often begin to rotate before this in occipito-posterior positions, since full "long restitution" through one and a half right-angles is so rarely seen. Quite a few degrees of rotation could cause a shoulder to move 1 in. (2.5 cm.) or 2 in. (5 cm.) or even more, and this could put considerable tension upon a cord already tight, quite apart from the other mechanism of descent mentioned above.

When these conditions obtain I believe a stillbirth may occur if the case is left too long "to Nature." When one would expect an easy delivery—the presentation, position, and contractions being good—and yet delivery is delayed, I believe one should suspect a tight cord. If the foetal heart becomes slow then forceps should be applied at once. I suggest that Mr. Reddington has not seen a stillbirth from "cord round the neck" because he is a careful obstetrician. If stillbirths do occur from this cause, perhaps they should be attributed to the neglectful midwifery which allowed a slowing foetal heart to pass unnoticed. In this sense the explanation of "cord round the neck" must be regarded with doubt. Since there is but little descent of the head before the os is fully dilated, after which the forceps may be used at any time (provided the head has entered the pelvis: and it will not have descended far if it is still floating), a timely forceps delivery should almost always save the baby. May I add that I doubt if the necessity arises often.

While on the subject of stillbirths resulting from accidents to the cord, I remember a young primigravida whose labour was progressing splendidly. Quite suddenly the foetal heart fell almost to 100 and became irregular. I at once applied forceps, and in adjusting the right blade distinctly felt the cord at the side of the head, but not prolapsed in advance of it. I have no doubt that it was being pressed between the head and the birth canal with each contraction. The child was not stillborn, but would have been, I am sure, if it had been "left to Nature." In this case the cord was not round the neck, and a stillbirth, had it occurred, would have been difficult to explain.

May I suggest, therefore, that while "cord round the neck" may rarely be an excuse for a stillbirth, yet it may nevertheless cause a stillbirth sometimes and should not be dismissed from our calculations. If it should be so dismissed, then that may encourage the less careful to neglect to listen to the foetal heart as often as they should towards the end of labour.—I am, etc.,

G. BENION THOMAS,
Professor of Midwifery, Madras Medical College.

Ocular Signs in the Prisoner of War from the Far East

SIR.—May I, as an ex-P.O.W. who had some experience of ocular defects among my fellow-prisoners in Hong Kong, make a few comments upon recent correspondence? Unfortunately I am not in a position to give statistics, but perhaps some general observations may be of interest.

The ocular signs for the most part corresponded to the description given by Spillane and Scott in the *Lancet* of Sept. 1, 1945 (p. 261), except that in addition we also saw a considerable number of conjunctival and corneal conditions, the latter varying from what appeared to be a mild epithelial dystrophy to ulceration (no slit-lamp observations were possible). These latter appeared to respond to cod-liver oil or vitamin A preparations.

A large proportion of men developed bilateral central scotomata with visual acuity ranging from less than 6/60 to almost standard vision. The field defects were central, and did not closely resemble those of tobacco amblyopia in shape or nuclei, but were for the most part roughly circular. The severer ones might show a central nucleus for a 10-mm. white object at 1 m. extending to 2 or 3 degrees from the fixation point, with roughly concentric zones for 5-mm. and 1-mm. white objects, or there might be no field for 1 mm. In others the defect might be only a relative one for red, and during the course of recovery in those who were fortunate a scotoma for white would regress to a relative scotoma for red. I personally was never able to follow a case to complete recovery, though I observed several who recovered 6/6 vision and were unaware of any defect.

My observations were made at 1 m. on a Bjerrum screen and not a perimeter. Only a few of the severer cases showed some peripheral contraction by the confrontation test. Those with dense scotomata frequently showed a concentric depression of the 1-mm. isopter to within the blind spot, and in some cases the 5-mm. isopter was demonstrably depressed. The blind spot was usually enlarged, but

the difficulties of accurate fixation may have accounted for this in some cases.

Pallor of the disk, usually only temporal, and always diagnosed with caution, manifested itself in a considerable proportion of those whose defect persisted for more than a few months, but, as Spillane and Scott found, the relation between the pallor and the severity of the defect was inconsistent. Pallor of the whole disk sometimes occurred, and in these the visual defect was grave, and probably permanent.

Macular changes were not uncommon, and usually took the form of minute pigmentary disturbances with or without small whitish dots, reminiscent of senile macular degeneration. I was unable to convince myself that there was any necessary relation between these appearances and the degree of central defect, as identical field defects were found in their absence.

The ocular condition was in most cases, as Dr. H. G. Garland observes (Jan. 26, p. 143), part of a neuropathic syndrome, which included in most cases varying degrees of spinal cord dysfunction, the worst cases being helpless and bed-ridden, and labelled subacute combined degeneration. A colleague in another camp reported a case which had all the appearance of a bulbar paralysis. He made an astonishing recovery, but I believe had a residual ocular defect. Nerve deafness occurred in a few, and I saw two cases of paresis of the vocal cords. Mental deterioration occurred in some, but may have had other causes than malnutrition.

The account given by Spillane and Scott of a similar syndrome in P.O.W.s in the Middle East is in many features applicable to our experience. We saw a similar neuropathy, but extremely painful feet were usually a prominent feature at some stage, and, as one would expect, universal and often extreme loss of weight. There were the same bizarre alterations of sensibility of the lower limbs, but frequently also in the trunk, upper limbs, and head and neck. There were commonly alternating zones of hyperaesthesia and anaesthesia of the chest and abdomen, associated with subjective sensations of constriction of the chest and abdomen, with difficulty of breathing and dysphagia. There was usually a sensation of numbness round the mouth, and frequently loss of anal sensation. The nervous control of the bladder reflexes was sometimes disturbed, leading to frequency of micturition or difficulty in starting the stream.

Ocular signs were not always present in these neuropathies, and conversely they sometimes were present without the remainder of the syndrome, but the association of the ocular and other nervous lesions was so frequent that it would seem unnecessary to multiply entities to account for them all. Furthermore, hypochlorhydria was clinically present in a large number, as shown by varying degrees of dyspepsia, flatulent distension, anorexia, and diarrhoea, responding to the administration of HCl when available. Anaemia was common, but facilities for blood examination were not generally available. It usually appeared to be of the hypochromic variety.

The frequent association of retrobulbar neuritis with hypochlorhydria, anaemia, and cord lesions, and the very high proportion whose neuropathy was preceded by diarrhoea or dysentery, perhaps suggests that the analogy to be drawn, at any rate in the Hong Kong cases, is not so much with the toxic amblyopias, as Capt. W. M. Rich (March 2, p. 330) would urge in his comments upon the extremely interesting paper contributed by Major G. C. Dansey-Browning and himself (Jan. 5, p. 20), as with a wider group including the sprues, anaemias, and subacute combined degeneration. I am not qualified to discuss the parts played by intrinsic and extrinsic factors, and I find the current textbook accounts of beriberi, pellagra, and central neuritis confuse my attempts to classify the condition under discussion, which does not appear susceptible of being neatly docketed under any of these labels. Elliot's *Tropical Ophthalmology*, like other pre-war writings, is also inadequate. One finally resorted to the non-committal term "avitaminosis." Capt. Rich refers to the "irreversible optic atrophy," but our experiences in Hong Kong indicated that there is an earlier stage when the optic nerve lesion and the other central lesions are to a greater or lesser degree reversible under slightly more favourable nutritional conditions.

We were not in a position to carry out any scientifically controlled experiments in treatment, but gave whatever vitamin preparations could be obtained or improvised, along with such extra protein and fat-containing foods as we were able to obtain by purchase, or to a greater extent by gifts from the local International Red Cross organization. The results so far as vision was concerned were frequently disappointing, though the earlier or less severe cases often benefited remarkably. Any attempts to evaluate different courses of vitamin therapy were inconclusive. Dr. Goldsmith's remarks are of interest in this connexion, as many of our patients declared that a course of eggs did their eyesight more good than anything else. One certainly felt that an egg contained something more valuable than any vitamin capsule. The Japanese ration was seriously deficient in protein. There was much confusion as to the cause of the oedema which was so common, but there is little doubt in my mind that what was frequently described as wet beriberi was hypoproteinaemic oedema. There was no apparent relation between the incidence of oedema and visual defects. The rice was often in poor condition and possibly

toxic. The absence of trachoma, where the disease is normally endemic, was also notable amongst the P.O.W. in Hong Kong.

In conclusion I should like to express the gratitude and admiration we all felt for the tireless work and self-sacrifice of all those voluntary workers among the non-interned residents of the colony who, often at great personal risk, and at the expense of their own health and treasure, obtained for us those extra supplies which were undoubtedly the means of saving many lives, and to whom many of us are to-day indebted for our health.—I am, etc.,

Leicester.

JOHN DURRAN.

Penicillin Treatment of Malignant Diphtheria

SIR,—I was interested to see the memorandum with this heading by Drs. A. B. Christie and J. C. Preston (March 23, p. 433). The aim in treating diphtheria with penicillin is to obtain: (1) a sufficient concentration in the blood; (2) a sufficient concentration in the saliva. The first is simple, the second requires a larger dose. In my opinion the dose should not be less than 500,000 units a day. This is sufficient to remove all penicillin-sensitive organisms from the mouth.

I have not seen enough cases to be dogmatic, but in the worst case that I have seen in my clinical experience and the worst case the medical officer of a fever hospital had seen, I gave a million units in the day. In all our opinions the prognosis appeared to be hopeless: a bull neck, an active spreading membrane in spite of antitoxin in adequate dosage (80,000 units intravenously), an ashy-grey patient in collapse, a very rapid onset with a rapid worsening of the condition. The organism was *C. diphtheriae gravis*. The response to treatment was dramatic, the membrane was coughed off intact in twelve hours, and the organism has not been grown since treatment was started. The child made a full recovery. Incidentally, the same dosage—500,000 units a day—seems to act equally dramatically in the few cases of scarlet fever that I have treated in this way, these cases being of the very severe anginose type seen in adults. In all cases treatment was stopped after three days.—I am, etc.,

St. Albans

DAVID A. LONG,
Penicillin Officer, Hill End Hospital

Tuberculin Therapy

SIR,—I should like to support Dr. John R. Gillespie's plea (March 30, p. 501) that there should be a fresh inquiry into this subject; the time for hammering out the truth is most fitting, now that its vigorous upholder has gone. Is tuberculin a unique prophylactic or invariably fraught with danger to the recipient? We, too, think that it has fallen into disrepute through no fault of its own. Now, administered according to Dr. Camac Wilkinson's method, it can do no harm, and it may do very much good in early uncomplicated cases of pulmonary tuberculosis. Started on infinitesimal doses of P.T.O. (*Perlsucht Tuberculin Original*) (bovine) the patient's response one way or the other soon becomes apparent; and, of course, on this depends the continuing or withholding of the treatment. Our working hypothesis may be simply stated thus. The aim is to desensitize the patient's tissues to the strong bacillary toxins which are forming tubercles in his lungs, this process being: mitosis of the connective-tissue cells, giant-cell formation, and subsequent devascularization of the whole tuberculous nodule. Bearing in mind, then, that the growth of the tubercle is essentially toxin-caused, we inoculate tuberculin into a healthy tissue with the express purpose of forming an antitoxin with which to neutralize the toxin of the bacilli, and thus to rob them of their only weapon. When thus safeguarded, the tissues in the front line are enabled to put up a fight, and separate themselves from the necrosed tissue. The zoned-off granulomatous material then further breaks down, and is coughed up as phlegm through the bronchioles, which act as natural drainage tubes. The rest of the treatment continues as a slow siege, until the desired cicatrization is reached.

That the administered heterotoxin may not exactly correspond to the autotoxin matters less than might be supposed. The danger is when the autotoxin becomes mingled with the toxins of pyogenic and other organisms. Unless these can be eliminated, it is useless and harmful to go on with the tuberculin. A question once frequently heard was, "Cannot an equally good result follow after absorptions of autogenous

tuberculin, more or less induced by graduated exercises?" The answer is that we have no control over the quality or quantity of this toxin, and indeed are in the dark as to whether it is functioning at all. Moreover, antitoxin formed from healthy cells has more to recommend it than that produced at a diseased focus.

We sum up by saying that tuberculin is primarily indicated in early cases of phthisis, uncomplicated by haemoptysis or marked pyrexia; and that it acts as a prophylactic by taking antitoxin-toll of the body cells, and thus follows the general law of immunization. The doses must be checked throughout by records of pulse, temperature, and weight; and, cautiously increased, both local and focal reactions can be kept at a safe minimum.

The danger of giving too heavy a dose of tuberculin, which, disastrously paralyses the immunizing agents of the body, must be attributed to carelessness rather than to faults of method. It was Koch's unfortunate early mistakes in this respect that dealt tuberculin therapy a knock-out blow, from which it seems never to have recovered.

The tuberculin course is, of necessity, lengthy, even with twice-weekly inoculations and things being at their best. The technique is sufficiently full of difficulties as to necessitate an initial course of instruction to those who wish to take it up. Above all, it must be remembered that everything depends upon the skill and judgment of the administrator.—I am, etc.,

Oxford

HERBERT C. MANNING.

SIR,—Dr. John R. Gillespie's letter on tuberculin therapy recalls the notable work of the late Dr. Camac Wilkinson. He achieved a great deal, and, I think, narrowly missed achieving a great deal more. To observers at his clinic one fact stuck out a mile. The patients insisted on the tonic effect of some of the doses. This raises the crucial point of the treatment dose of vaccine, which has never been appreciated at its proper worth. Vaccine is so firmly associated in the minds of most doctors with prophylaxis that it has proved a curse when treatment is the object, not prophylaxis. A correct treatment dose is as remarkable in its effect, and often as rapid, as is that of opium, digitalis, or other potent drug. Who in his senses would go on increasing the dose of a powerful drug when it is acting satisfactorily? Yet how often do we get instructions to do so when vaccine is being used? A dose of vaccine, if in any way effective, produces either a reaction, which is not the object, or a beneficent response, and this latter effect is what one aims at. Dr. Gillespie has no easy task ahead, but he has my sincerest wishes for success.—I am, etc.,

Crowborough

G. L. BUNTING.

B.C.G. Vaccination

SIR,—In his communication (March 30, p. 501) Dr. Claude Lillingston wonders "if we have been caught napping" with regard to B.C.G. It would not be fair to say that, though we have been slow to appreciate the use which has been made of it in other countries. However, in November, 1943, as a result of a meeting of the Tuberculosis Association, at which physicians from Norway, Canada, and the U.S.A. spoke, a joint committee consisting of representatives from the Joint Tuberculosis Council, the Tuberculosis Association, and the National Association for the Prevention of Tuberculosis was set up to investigate the position. While the war lasted there did not seem any possibility of trying out B.C.G. here, but in the near future action will be taken to put the case for its trial before those in authority and before the medical public.—I am, etc.,

The Tuberculosis Association,
26, Portland Place, London, W.1.

J. V. HURFORD.

SIR,—Dr. Claude Lillingston in his letter on B.C.G. vaccination (March 30, p. 501) asks whether we have an "intelligent Intelligence Service" to keep us from being "caught napping" by medical advances in other countries. In your answer you refer him to your leading article of Dec. 4, 1943. You are too modest. Dr. Lillingston quotes an eminent Scandinavian authority as saying: "The stage at which one discussed the risks of B.C.G. having been passed, the questions now remaining to be asked are: whom to vaccinate, and how long does the immunity conferred by B.C.G. last?" This was on Jan. 18

of this year. On Oct. 7, 1934, in a review of my book on B.C.G., in which I advocated it as safe and successful, you said: "These views are very similar to those which have been advanced in the editorial columns of the *B.M.J.* during the past few years, and are likely to meet with a considerable measure of approval. The real crux of the matter is how great and how lasting is the degree of immunity produced."

I think Dr. Lillingston's fears are justified; we have been caught napping in this country—but not through any fault of yours, Mr. Editor, or mine.—I am, etc.,

Henley-on-Thames.

K. NEVILLE IRVINE.

Temperature in Pulmonary Tuberculosis

SIR,—There have been a number of articles in the *Journal* about the temperature in pulmonary tuberculosis, especially in connexion with the menstrual cycle: Feb. 9 (p. 209), March 2 (p. 334), and April 6 (p. 523). In the *Journal* of Dec. 29, 1928 (p. 1173), I wrote on "The Temperature in Pulmonary Tuberculosis."

The oral method is the most suitable for taking the temperature, but the patient must keep his or her mouth shut for fifteen minutes, and the thermometer should be kept in for five minutes for accuracy. I noted the following points. (1) There was a definite premenstrual rise in temperature, the average duration of which was five to six days. The long premenstrual rise is present in only 34% of positive cases, but in 52% of negative cases. Two healthy nurses took their own temperatures at my request, and in both cases there was a premenstrual rise. This seems to show that it is not diagnostic of tuberculosis. In fact, if only one record of temperature is taken, it must be considered in relation to the menstrual cycle. (2) I also noted that in 90.1% of males the difference between morning and evening temperatures was more than 1° F. (0.56° C.), and in 56.7% of females less than 1° F.—I am, etc.,

Dorridge, Birmingham.

COLIN MILNE.

Stethoscope versus X Rays

SIR,—Dr. J. Frankland West (Feb. 2, p. 182) describes a case in which the radiological diagnosis was that of a resolving lobar pneumonia, though the patient actually was suffering from pulmonary tuberculosis. From this case Dr. West concludes that a vote of "no confidence" with regard to mass miniature radiography is justifiable, and also that the x-ray film is inferior to the stethoscope in the diagnosis of early tuberculosis. Frankly I fail to see how a medical man with years of training behind him can arrive at such a conclusion on the scanty and feeble evidence put forward.

The clinician who relies on others for his x-ray interpretations is apt to forget that we can ask an x-ray film—and particularly one of the chest—just so much and no more. He feels that in order for such a film to be of any use it must supply an exact answer to the question, "From what disease is this patient suffering?" This belief is often fostered by the unwary radiologist who is tempted to read his films in terms of "radiology" instead of "pathology."

The x-ray film is a shadow picture of a disease process in an anatomic structure, and often cannot, and should not, be interpreted in the light of the causative organism. Yet this apparently is what Dr. West feels that it should be capable of doing before he is willing to grant it its rightful place in chest diagnosis. He is asking too much of his chest films, and because on occasions he gets the wrong answer he is ready to condemn the most useful diagnostic means at our disposal. Would Dr. West drive a screw with a hammer? And if he did try to do so without success would he then condemn the hammer as a useless tool? Would he condemn the microscope because it failed to tell him the difference between a tubercle bacillus and, say, a leprosy bacillus?

Nevertheless he attempts to belittle the value of the x-ray film when he once fails to get from it a differentiation between a tuberculous pneumonia and a resolving lobar pneumonia, two conditions which may very strongly resemble one another. Any man with experience of chest radiology will admit that such differentiation is often quite impossible, and in Dr. West's case I have no doubt at all that the fault lay, not in the x-ray film, but in too great a readiness on the part of the radiologist

to give a definite diagnosis on insufficient evidence. Those of us who give our whole time to chest work are constantly running across difficulties in accurate diagnosis on the basis of the x-ray film alone. A lung abscess may look exactly like a tuberculous cavity, while malignant glands in the mediastinum may be indistinguishable from the glandular involvement due to primary infection tuberculosis.

Nevertheless the x-ray film may be relied upon to reveal with accuracy pathological changes in the chest, even though on some occasions it gives no clue to the aetiology of the condition encountered. As a clinician who for the last fifteen years has been listening to patients' chests first and examining their x-ray films afterwards, I have no hesitation in saying that the skiagram will reveal many more early lesions than my stethoscope will bring to light. I use the word "lesions" advisedly, however, as in a number of cases it is impossible to be sure of the actual condition present without further laboratory and clinical examinations, and often another x-ray examination.

Dr. West has missed the point entirely when he expects a cut-and-dried diagnosis always to stare at him as soon as he opens the radiologist's report. Surely he would not ask for a vote of "no confidence" in his own report when it failed to recognize a three-foot depth of water. Yet this is exactly what he is doing when he asks an x-ray film too much and occasionally gets a wrong answer.—I am, etc.,

King George V Jubilee Memorial
Sanatorium, Jamaica.

RICHARD A. S. CORY,
Senior Medical Officer.

SIR,—I hasten to explain that the membership of my "fifth-rate provincial soccer club" (March 16, p. 410) was strictly limited to the clinical methods of investigation which were enumerated in the preceding paragraph. Persons—living, dead, or fictitious—were neither admitted nor included. I hardly thought that this explanation would be necessary, but Dr. Weatherhead's letter (March 30, p. 504) shows that one can never be too careful when using a comparison.

Dr. Weatherhead's statement that I am a "comparatively recent" recruit to the tuberculosis service is not only comparatively but absolutely untrue. If ten years—three and a half of which were spent in full-time hospital appointments (two years in a teaching hospital) and six and a half years in busy tuberculosis clinics—come under the heading of "comparatively recent" then I must admit that my English is considerably worse than Dr. Weatherhead thinks.—I am, etc.,

Woodford Green, Essex.

F. KELLERMANN.

Words and Clear Thinking

SIR,—I read with considerable interest Dr. T. C. Beard's letter (March 16, p. 404). It seems to me that medicine is honeycombed with etymological inconsistencies, in many cases the same word showing a Greek prefix and a Latin suffix, such as that dreadful word "dysfunction." Surely it would be better to show lingual continuity by referring to a "malfunction" or "dyscrasia."

It would be useful if some efforts were made to standardize medical language. Two glaring examples of mental confusion are presented in the numerous alternative names for the barbiturate drugs and in the various pathological subdivisions of the nephritic lesion such as "acute diffuse glomerulo-tubular nephritis." As I once heard a learned physician say, "Azotæmic and hydraemic nephritis are good enough for me." Again, why in eliciting signs in the chest should it be said that "vocal fremitus" is increased or diminished, thus using an English and a Latin word in the same phrase? Or is it really to one's advantage to know that splenomedullary leukaemia is synonymous with myelocytic leukaemia? I well recall on a ward-round my chief reading out to us clerks the registrar's impressive differential blood count in which well over a dozen different types of cell were claimed to have been seen under the microscope. Among them was a group classed as "dictocyte." My chief, himself a blood expert, said blandly to us: "Dictocytes! What are they? Do they talk to you?" There is a tendency also to fix the incorrect proper name to certain things. In descriptions of lymphadenoma the giant cells are labelled *Dorothy Reed or Sternberg cells*, whereas they were first described by Sir Frederick Andrewes of Bart's and should be Andrewes cells. To give another example, Graves's disease was

first described by C. H. Parry, a West Country physician of repute.

Basic English has a lesson to teach us, I feel sure, in helping one to express oneself in a simple manner. Muddled thought leads to muddled action and has been responsible for not a little of the present international unrest, and for vague terminology in so many official documents, such as White Papers, that one meets nowadays. If everyone "called a spade a spade" the affairs of nations would soon sort themselves out in a reasonable manner.—I am, etc.,

Donibristle, Dunfermline.

J. B. GURNEY SMITH,
Surgeon-Lieut., R.N.V.R.

Obituary

CHALMERS WATSON, M.D., F.R.C.P.ED.

We regret to announce the death on April 6 at Fenton Barns, Drem, East Lothian, of Dr. Chalmers Watson, consulting physician to the Edinburgh Royal Infirmary, who had been well known for his work on nutrition and in later years devoted himself to rearing cattle for production of pure and safe milk.

Douglas Chalmers Watson, son of Walter Watson, M.D., of Midcalder, was born in 1870 and was educated at George Watson's College and at Edinburgh University, where he won the Wightman prize in clinical medicine on graduating M.B., C.M. in 1892. After serving as house-physician at the Royal Infirmary and at the Royal Hospital for Sick Children he was elected F.R.C.P.ED. in 1901 and proceeded to the M.D. in 1904. For a time he worked on nutritional problems in Sir Edward Sharpey-Schafer's laboratory, and for this research he was awarded the Alvarenga prize by the College of Physicians of Philadelphia. After his election to the visiting staff of the Edinburgh Royal Infirmary Chalmers Watson was active in promoting scientific methods in hospital practice; he exercised much influence upon students as a clinical teacher and became senior lecturer in clinical medicine in the university. He joined the B.M.A. in 1897 and was secretary of the Section of Pharmacology and Therapeutics at the Annual Meeting held in London in 1910. He was the original editor of the *Encyclopaedia Medica* published in fourteen volumes at the beginning of this century, of which a second edition appeared in 1915-25. His numerous published writings included *Food and Feeding in Health and Disease*, which reached a second edition in 1913, and a small volume, *Lectures on Medicine*, a handbook for nurses; also *The Book of Diet*. A clear and fluent writer, he was a strong advocate of reform in medical education and keenly interested in student activities, both athletic and social. At the Edinburgh University Rectorial Election in 1935 he ran Lord Allenby close.

His first wife, Alexandra Mary Geddes, C.B.E., M.D., sister of Lord Geddes, took a prominent part in Scottish public life and shared many of his tastes and activities. She had been physician to the Edinburgh Hospital for Women and Children, chief controller of the Women's Army Auxiliary Corps, and president of the Medical Women's Federation. She died in 1936, and he married secondly Miss Lily Brayton, widow of Oscar Asche.

The following passages are quoted from a tribute paid to Dr. Chalmers Watson by a colleague writing in the *Scotsman*:

His originality of thought and dynamic spirit early created an impulse towards research. As a physician associated with the Royal Infirmary of Edinburgh throughout his active medical career he was a clinician of outstanding ability. He was equally loved for his humanity and respected for his sincerity and integrity of purpose. He inspired succeeding generations of students by his enthusiasm, his clarity of exposition, and his originality of thought. He had deep insight into human nature and an unusual capacity for imparting it to others. To his clinical work in hospital he brought his earlier scientific training and was responsible for founding the clinical laboratory of the Infirmary. In the sphere of social medicine his interest was equally wide and the effect of his endeavours equally impressive. Perceiving the lack of suitable institutional facilities for the treatment of those of moderate means he obtained the charter for the foundation of the Queen Mary Nursing Home in Edinburgh and led the way to numerous similar developments elsewhere. Faithful to his early instinct in nutrition as a basis of good health he was not only an ardent advocate of healthy food production, but, in later years, took a practical lead in dairy farming.

Dr. WILLIAM HERBERT SMAILES, who died on March 24 in the Brotherton Wing of the Leeds General Infirmary, was for many years an active worker in the British Medical Association. He had been chairman of the Huddersfield Division and president of the Yorkshire Branch; he served a year on the Central Council and nineteen years on the Insurance Acts Committee, and represented his Division at thirteen Annual Meetings of the Association. Born at Honley, near Huddersfield, on July 6, 1881, son of Thomas Smalles, M.D., he was educated at the Leys School, Cambridge, and at Manchester and Leeds Universities. He graduated M.B., Ch.B. of Leeds, and M.B., B.S. of London University in 1905, took the M.D. (London) in 1910, and the D.P.H. of Sheffield in 1912. Dr. Smalles had been in practice at Honley for forty years. He was medical officer at the Deanehouse Institution, held many public appointments, and was for some time honorary pathologist at the Huddersfield Royal Infirmary. During part of the war of 1914-18 he worked as assistant surgeon at the Huddersfield War Hospital with the rank of captain, R.A.M.C.(T). He was a past president of the Huddersfield Medical Society and honorary secretary of the Panel Committee. Apart from his medical work, Dr. Smalles had many other activities. He was a J.P. for the West Riding of Yorkshire, a member (ex-chairman) of the Holmfirth School, and a prominent Freemason. H.F.H. writes: His passing has removed from this district an outstanding figure. After nearly seven years of close association with him on the National Service Board at Huddersfield, I can, with knowledge, pay tribute to his worth. He was a fine clinician, of mature and balanced judgment, a most careful and courteous examiner, and a delightful colleague. No matter how busy he might be in his practice, he was invariably punctual in his attendances at the Medical Board, his work was never hurried, and he never lost his serenity. Always ready to help his colleagues, he had a smile and pleasant word for everyone, and was loved by us all. It is not to be wondered that his patients were devoted to him, his life being spent in their service. He was an example of the ideal family doctor, and his passing has left a void which it will be difficult to fill. To his widow and family we extend our deepest sympathy.

Dr. DUGALD CAMPBELL ORR, M.C., who died in hospital at East Kilbride on March 25, graduated M.B., Ch.B. at Glasgow University in 1926. A. B. S. writes: On learning of the death of Dr. Dugald Orr I felt keenly the loss of a great friend and a great physician. My association with him extended over a short nine months, when as a very green house-physician it was my happy lot to be under his masterly guidance. His knowledge of the management and treatment of pulmonary tuberculosis had an uncanny completeness and breadth. But his real mastery lay in his deep sympathy with and understanding of an afflicted human being rather than an afflicted lung. It was this ability to understand and analyse human reactions that made him a great physician. Despite an incapacitating illness he struggled on heroically—his first concern always being the care of his patients. Not only the medical world but also all those privileged to fall under his care will mourn the passing of this beloved physician.

Dr. LEWIS TURNER LANCASTER, of Clitheroe, Lancs., died on March 26 at his home, after a short illness, at the age of 80. He graduated M.B., C.M. at Edinburgh in 1890, and succeeded his father in 1893 in an extensive and scattered country practice in the Clitheroe district. He was in active practice for 40 years: 20 years with horses over long distances, and 20 years with motor cars doing N.H.I. work. He referred to the first 20 years as the good years, the harder years, when work was difficult, responsibilities heavy, hospital facilities scanty—the years when services were appreciated. He found it hard to adjust himself to the psychology of the N.H.I. patients who crowded his surgeries and wasted his time. He was a man of strong individual character, of artistic tastes, loyal, sincere, kind and genial, but hostile and impatient in the presence of his wife and daughter, there was a cordial welcome to all friends who came to see him. He was well known to all friends and practitioners of N.E. Lancs. and to a wide circle of friends in this district. He was a member of the B.M.A. for the last 50 years. The writer has worked with him as an assistant, as a partner, and succeeded him in his practice 15 years ago. Throughout these years he remained the same staunch friend and counsellor, sound and solid and true—qualities which his colleagues in practice respected throughout his active career. He loved a joke and could pass one on with relish. His reminiscences of his early days in practice were highly entertaining. He has gone from among us, but the memories of a vivid personality remain.—J. M.

Dr. GEORGE GUNN, of Neston, Cheshire, died on April 3 at Crowborough, Sussex. He was born in Melbourne in 1879, and from the Church of England grammar school in that city came to this country to study medicine. He graduated M.B., Ch.B. of Edinburgh University in 1905, and in 1908 proceeded M.D. and took the F.R.C.S.Ed. diploma. By that time he had held house appointments at the Edinburgh Royal Infirmary, at the Royal Southern Hospital, Liverpool, and at the Royal Edinburgh Children's Hospital. Before settling in practice at Neston he served as resident medical officer at the Kasr-el-Ainy Hospital at Cairo. During the war of 1914-18 he was medical officer to the Red Cross Hospitals at Thingwall Hall, Parkgate, and Neston, and later M.O. to the local war memorial cottage hospital; he was awarded the M.B.E. in 1920. Dr. Gunn had a particular interest in paediatrics and was for some years physician to the Heswall Branch of the Royal Liverpool Children's Hospital. He joined the B.M.A. in 1911, and became chairman of the Birkenhead Division in 1922.

The Rev. SANDFORD SCOBELL LESSEY, M.D., rector of Grafton Underwood, Kettering, who died on April 3, spent a large part of his life as both physician and clergyman. He was born in London on Feb. 21, 1859, son of Theophilus Lessey, and studied medicine at St. Thomas's Hospital, qualifying in 1882. For seven years he was a member of the staff of the Miller Hospital and Royal Kent Dispensary and surgeon to the New Cross and Deptford Provident Dispensary. In 1896 he entered a theological college, and in 1899, the year in which he took the M.D. degree of Durham University, became curate of Newport, Isle of Wight. From 1902 to 1912 he was vicar of Hythe, near Southampton, and then for four years chaplain-superintendent, under the Church of England Temperance Society, of the Temple Memorial Home for Male Inebriates at Cinderford. During the war of 1914-18 he took charge of several medical practices so that doctors could join up, and he afterwards practised at Birmingham. In 1935 he accepted the living of Grafton Underwood, a tiny parish in Northamptonshire with a population of 200, which had had no rector for seven years because the stipend was too small for anyone but a man with independent means to accept the office. The money Dr. Lessey received for the sale of his practice or saved during his lifetime enabled him to take the living, to which he was inducted by the Bishop of Peterborough on April 30 of that year. He had joined the B.M.A. in 1894.

Dr. EDWARD HENRY EZARD, who died at Farnham, Surrey, was born at Bath on Aug. 15, 1864, son of Henry Ezard; he was educated at Grosvenor School, Bath, at Bristol, and the University of Edinburgh, where, after graduating M.B., C.M., and B.Sc., he was demonstrator of physiology for a year, and then for two years assistant physician to the Royal Edinburgh Asylum. He received the D.Sc. degree in Public Health in 1893. Later he went to Cambridge, took the M.A., and became director of medical studies at FitzWilliam Hall. Before his retirement from active work Dr. Ezard held honorary ophthalmic appointments in and around Cambridge, and during part of the war of 1914-18 served as civilian eye surgeon of the 1st Eastern General Hospital. He joined the B.M.A. in 1885, was a Fellow of the Royal Historical Society, and a past president of the Royal Medical Society of Edinburgh.

The death of the Rev. JAMES KITCHIN, L.R.C.P.&S., breaks a link with the older generation of medical missionaries in India. After spending some years in practice at Leven, Fife, Dr. Kitchin was able to fulfil a long-cherished hope when, in 1905, he was appointed by the former United Free Church of Scotland to the Mission to the Santals, an aboriginal tribe inhabiting the uplands of Chota Nagpur in Bihar. There he had as one of his colleagues Dr. J. M. Macphail, who was then building up a wide reputation as an ophthalmic surgeon in that part of India. Kitchin soon felt the urge to break new ground, and eventually he established a hospital at Tisri, where he spent over 25 years of service. He was a man who in a singular degree combined with his medical skill a deep and sincere piety and an unflinching compassion for the sick folk who filled his hospital—qualities that had their roots in a simple Christian faith. His courtesy, too, was unflinching. In addition to his medical work he did much to advance the cause of primary education among the Santals, and often, after a long day in hospital, he would go out to visit one or other of the night-schools which he had established in neighbouring villages. He spent himself unsparingly in the service of the people, who learned to trust him not only as a doctor but as a counsellor and helper in any of the manifold troubles which are the lot of the poor all over India. He was nobly assisted by his wife, who shared his constant devotion to the work of the Mission. He retired in 1935, and after Mrs. Kitchin's death three years ago he had been in failing health. James Kitchin was truly in

the succession of the holy and humble in heart whose lives have refreshed the earth. He lives in the memory of many simple folk who counted him their friend and in the affectionate regard of his colleagues in the Mission.—W.D.

The work and influence of J. D. ROLLESTON, writes Dr. A. P. Cawadías, were much more important than they appeared. Like his brother, he took the broad humanistic view of medicine. He was not only a medical historian but also a physician of wide culture who wanted to infuse medical practice with the high intellectual background of the Renaissance physicians. It was because he proceeded from such depths that he showed such manifold interests. But his epidemiological, his paediatric, and his social medical work were united by a common humanistic basic conception. Undoubtedly his influence has been great in fostering this conception so necessary in times when politics, the pressure of material interests, and the mechanization of life threaten to undermine this intellectual basis without which we shall degenerate into blind craftsmen. Those who, like myself, were intimately associated with J. D. Rolleston can testify to his high aims, to his tenacity and courage. He had not, however, the reputation he merited, for he lacked the self-confidence and the external strength to "blow his own trumpet." And he was handicapped also by the gigantic figure of him whom he called "my famous brother." I have been honoured with the friendship of both the Rollestons for more than twenty years, and I believe that the only difference between them was one of personality. Both, however, should be united in the history of British medicine as torchbearers of the humanistic tradition.

The Services

Capt. V. S. Joshi, I.A.M.C., has been awarded the M.C. in recognition of gallant and distinguished services in the Far East.

Col. J. T. Simson, late R.A.M.C., has been mentioned in despatches in recognition of gallant and distinguished services in the defence of Hong Kong in 1941.

The following have been mentioned in despatches in recognition of gallant and distinguished services in North-West Europe:

Cols. W. D. Anderton, M.C., C. D. M. Buckley, M.C., and J. W. C. Stubbs, D.S.O., M.C., late R.A.M.C. Brig. (Temp.) H. L. G. Hughes, C.B.E., D.S.O., M.C., Brig. (local) A. E. Porritt, C.B.E.; Cols. (Temp.) L. T. Fumivall, D.S.O., and W. A. Robinson, O.B.E.; Col. (Acting) R. W. Fairbrother; Lieut.-Col. A. Harrison-Hall; Lieut.-Cols. (Temp.) W. M. Arnott, T.D., J. H. Bolton, A. L. Eyre-Brook, C. L. Broomhead, T.D., J. Clay, P. Coleman, T. H. Crozier, G. V. Davies, T. H. Dockrell, L. H. Howells, A. F. Kennedy, O.B.E., J. C. Lindsay, M. J. Lindsey, M.C., M. Markowe, N. H. Martin, T. Moore, R. J. G. Morrison, F. Murgatroyd, E. A. L. Murphy, T.D., J. W. Osborne, W. M. Oxley, G. D. Pirrie, C. B. Prowse, W. A. McD. Scott, J. Shields, C. de V. Short, R. A. Smart, R. A. Stephen, J. P. Stewart, W. Stewart, M.B.E., and A. D. Young, D.S.O.; Majors E. H. Evans, J. A. C. Fleming, E. R. Hargreaves, and B. F. Longbotham; Majors (Temp.) J. MacC. Almond, E. McL. Barbour, J. Borrowman, R. Y. Bullock, A. A. Byrne, M.C., G. G. Cochrane, H. H. Collier, J. L. Collis, R. C. Cunningham, G. H. Darke, W. N. Darling, F. R. Dennison, W. N. Douglas, R. Glanvill, G. Gregg, A. B. Hamer, J. M. Harker, M.B.E., J. C. Harland, G. J. Harrison, S. T. Henderson, J. A. Hewitt, S. Howe, W. Hynes, J. E. Marquis, R. J. Miller, W. G. Mills, C. R. Morgan, R. T. Nicholas, D. J. Paddison, K. D. G. Reid, I. B. Rees-Roberts, J. A. Ross, J. E. Roys, G. R. Royston, G. Sanders, R. S. Thompson, H. Hall-Tomkin, M. Toohey, A. M. Wadsworth, F. R. Waldron, J. Watt, M.C., L. R. West, H. F. Whalley, A. R. Wilson, M.C., and J. W. Wishart; Majors (Acting) W. J. Christie, and H. S. Lanceley; Capt. E. Anderson, J. Anderson, J. D. Binning, R. Black, J. N. Blair, F. M. Braines, J. M. Childs, S. S. Conlan, P. J. Cremin, W. R. Cunningham, (Mrs.) M. W. Davies, R. D. Dewar, A. H. Dickie, W. K. Douglas, A. R. Ford, W. G. French, T. Gibson, W. N. Gibson, D. H. Girdwood, (Miss) M. B. Graham, A. Hughes, R. T. Kiddie, H. W. Lees, R. Levy, M. P. Lewis, N. A. Lewtas, E. MacLaine, O.B.E., A. D. Macrae, J. D. McCardell, R. C. McLaren, T. H. Meek, C. Milne, J. F. O'Neill, G. W. Pimblett, (Miss) D. P. Potter, E. J. T. Prettjohn, D. H. Rhind, P. M. Ritchie, T. T. Romans, (Miss) O. C. Sandys, W. M. Smith, D. N. Stuart, J. H. Tasker, J. R. Trowne, I. McC. Troup, H. B. S. Warren, P. F. A. Watkins, C. J. L. Wells, W. F. White, O. P. G. Whitfield, I. A. Williams, and W. K. Young; Capt. (Temp.) W. H. Franklin, and J. Wilson; Lieuts. J. G. S. Burton, F. A. Donnthorne, S. B. Fletcher, K. D. Poulter, W. A. Reynolds, K. L. Taylor, A. H. Tottle, C. Weir, and S. J. Windsor, R.A.M.C.; Lieut.-Col. J. M. Spence; Majors (Acting Lieut.-Cols.) F. S. Brion and W. M. Couper; Majors H. W. Fish, E.D., E. W. Flahiff, S. Hanson, E. A. Lovell, A. B. Sinclair, E. G. Spooner, C. R. Trask, and K. J. R. Wightman; Capt. (Acting Majors) R. Cowan, and R. MacK. Taylor; Capt. J. B. Benson, R. F. Boettger, B. L. P. Brosseau, M.C., B. W. Casselman, J. N. Cunningham, T. Dalrymple, R. E. Fisher, J. H. S. Geggie, J. Greenblatt, J. E. Howes, S. Kling, G. B. McCall, J. S. S. Martin, S. M. Medine, J. K. Morrison, R. D. Oatway, J. E. G. Soucie, and J. B. Tindall; Lieut. D. P. Melville, R.C.A.M.C.

NAVAL MEDICAL COMPASSIONATE FUND

A meeting of the subscribers of the above Fund will be held on April 26, at 3 p.m., at the Medical Department of the Navy, 64, St. James's Street, S.W.1, to elect six directors of the Fund.

Medical Notes in Parliament

Development of Atomic Energy

On March 28 Mr. MARTIN LINDSAY opened a debate on the industrial development of atomic energy. He said scientific opinion on both sides of the Atlantic agreed it would be feasible to have atomic power at an economic price within about ten years. Provision in large quantities of radioactive substances would be of great value for medical and biological research and might result in new cures for diseases.

Mr. BLACKBURN said Prof. E. L. Lawrence, of California University, had stated that the first use to which the giant cyclotron in California would be put was research into and treatment of cancer. Prof. Lawrence expected valuable results in two or three years. By the use of radioactive isotopes, which could be fed or injected, it would be possible to discover the metabolism of the human body as never in the past. It would be possible to discover what made a cell grow; thus it might be possible to discover the cause of cancer. By the plutonium process one was able to extract in bulk radioactive substances and radiations vital in medical research and therapy.

Mr. JOHN WILMOT, in reply, said the problem of harnessing the energy of the atom for peaceful purposes had not been solved. Atomic energy plant produced an intense radiation—lethal if it was not screened. Benefits to medical science by the use of artificially produced radioactive materials might have immense value. In nuclear reaction about 1,000,000 times more energy was liberated from a given weight of matter than in any known chemical reaction. There seemed to be no limits to the contribution to human progress which this development might produce.

Veterinary Practice

Mr. TOM WILLIAMS, replying on April 1 to Mr. S. Hudson, said the Government welcomed the recommendations of the Loveday Committee on Veterinary Education in Great Britain and of the Chancellor Committee on Veterinary Practice by Unregistered Persons. It was intended to introduce legislation empowering the Privy Council to authorize a university to confer degrees entitling the holders to registration with the R.C.V.S. as veterinary surgeons. The Bill would also provide for the reconstitution of the Council of the R.C.V.S., would provide for that Council to exercise powers of inspection of teaching facilities and examinations at all veterinary teaching centres, and would deal with the subject of veterinary practice by unregistered persons. The Government would be prepared to provide substantially increased financial assistance to veterinary education. Legislation could not be introduced immediately.

Scrub Typhus

On April 2 Mr. LAWSON told Mr. Viant that the first batch of scrub typhus vaccine was dispatched to India in June, 1945, and by December, 1945, 268,000 ml. had been dispatched. Information was not at present available in the War Office of the number of men inoculated, and information as to the number of cases related only to 1944 and 1945. The following figures of cases of scrub typhus were reported to the War Office for the years 1944 and 1945.

	1944	1945		1944	1945
January ..	100	291	July ..	133	210
February ..	22	40	August ..	835	157
March ..	Nil	—	September ..	684	111
April ..	3	39	October ..	723	177
May ..	35	24	November ..	677	120
June ..	46	79	December ..	530	65

Enteric Fever in the Army

Mr. LAWSON regretted on April 2 that complete figures of cases of enteric fever and deaths from that disease in British armies during the war were not available. He furnished the numbers of cases for four Commands during stated periods as follows:

United Kingdom (September, 1939–December, 1945)	210
M.E.F. (1941–4)	789
	(87 deaths)
C.M.F. (1943–5)	622
B.A.O.R. (July–December, 1945)	29
	1,650

Except in the case of M.E.F., no figures of deaths were available. The figures related to the enteric group of diseases, which included typhoid fever, paratyphoid fever A, B, and C, and "clinical typhoid."

Malaria Control

Mr. LIPSON on April 3 asked if the attention of the Secretary for the Colonies had been drawn to the report by the Ross Institute that conditions in Malaya with regard to malaria

control had reverted to those of 25 years ago. Mr. GEORGE HALL said he had seen this statement. The military administration of Malaya appreciated the serious effects of Japanese neglect, and, within the limitations of man-power, supplies, and transport, pushed on with the restoration of malaria control in the larger centres of population. The Advisory Malaria Board had been reconstituted. It was the intention of the civil medical authorities, who had taken over, to press forward not only with emergency measures of oiling and the distribution of drugs but also with the reconstruction of the antimalarial works which did so much to reduce the incidence of malaria in pre-war Malaya.

Lady NOEL-BUXTON inquired on the same date whether the Government of Tanganyika had adequate machinery for co-ordinating malaria control schemes on sisal estates. Mr. GEORGE HALL said co-ordination of malaria control schemes on sisal estates in Tanganyika formed part of the general public health service of the Territory. This service was not yet fully effective owing to the acute shortage of staff in the medical department. Recruitment to fill existing vacancies in the establishment of the department was proceeding as rapidly as possible.

Universities and Colleges

UNIVERSITY OF MANCHESTER

The following candidates have been approved at the examination indicated:

THIRD M.B., CH.B.—*Pathology and Bacteriology*: Barbara Anderson, Doreen M. Ashworth, Kathleen Barr, P. J. Crawford, K. A. Eshenigian, Ruth Goodier, H. Jackson, V. T. Mason, Mrs. Barbara Oldham, J. E. Parry, R. J. A. Webb, Doreen Wilkinson, D. H. Wright.

UNIVERSITY OF EDINBURGH

Dr. Douglas Guthrie will give a series of lectures on the history of medicine in the physiology class-room of the University on Mondays, at 5 p.m., from April 22 to June 24, both dates inclusive. The title of his first lecture is "The Material and the Tools"; details of the other lectures will be announced in the diary column of the *Supplement* week by week. They are free to all matriculated students; 10s. to others.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

The following candidates have satisfied the examiners for the Diploma in Obstetrics of the College:

Pamela M. C. Aitchison, O. Amadori, Sheila M. Baker, J. Baron, Elizabeth Bate, Margaret E. M. Buxton, Doris Brighton, R. W. Burslem, Jean Collins, Constance M. Cowan, J. Cox, Doris A. Craigmile, G. M. Evans, W. Hall, N. J. P. Hewlings, H. A. Hewlett, G. I. Isaacs, S. M. Jenner, C. M. Kamdar, J. D. Martin, T. Miles, Alice K. Montgomery, J. K. Oaden, J. A. Partidge, Charlotte Saba, J. W. Smith, W. W. Willson.

Medical News

The annual meeting of the Association of Surgeons of Great Britain and Ireland will be held at the Royal College of Surgeons, Lincoln's Inn Fields, W.C., on Tuesday and Wednesday, May 7 and 8. On the first day, after the election of officers and other business, a discussion on inguinal hernia will begin at 10.15 a.m. In the afternoon short papers will be read, followed by tea at Apothecaries' Hall and dinner at Claridge's Hotel. On May 8 a discussion on "Chronic Osteomyelitis, the Sequel to a Gunshot Wound," will begin at 10 a.m., and operating sessions are being arranged at a number of London hospitals in the afternoon. Copies of the programme are issued from 45, Lincoln's Inn Fields, W.C.2.

A meeting of the Medico-Legal Society will be held at 26, Portland Place, W., on Thursday, April 25, at 8.15 p.m., when a paper will be read by Mr. William Latey on "Consummation of Marriage and the Law."

The Société Française de Dermatologie et de Syphiligraphie will hold a special meeting devoted to the treatment of cutaneous tuberculosis by vitamin D, in high dosage at 10 a.m. on May 8, at the Museum, St. Louis Hospital, Paris. The committee of management would be very happy if some members of British dermatological societies could attend the meeting. An ordinary meeting of the society will take place on May 9 at 9.30 a.m., at which also they would be welcomed. The secretary-general is Dr. R. Degos, 20, Rue de Penthièvre, Paris, 8.

The annual general meeting of the Faculty of Ophthalmologists, whose new council has now been elected, will be held at the house of the Royal Society of Medicine, 1, Wimpole Street, W., on Saturday, June 1, at 2.30 p.m. Notices will be sent to each member and associate of the Faculty, with a copy of the annual report.

A special meeting of the London Association of the Medical Women's Federation will be held at B.M.A. House, Tavistock Square, W.C., on Thursday, April 25, at 8.30 p.m., when there will be a discussion on the National Health Service Bill.

Lord Horder presided at a dinner at the Savoy Hotel on April 5 in celebration of the 150th anniversary of the Abernethian Society, which succeeded the Medical and Philosophical Society of St. Bartholomew's Hospital, founded in 1795. The speakers included Sir Alfred Webb-Johnson, President of the Royal College of Surgeons of England, Surg. Rear-Admiral C. P. G. Wakeley, president of the Harveian Society, and Mr. Douglas Abernethy, surgeon to the Radcliffe Infirmary, Oxford, whose great-grandfather was John Abernethy's nephew.

The president of the American Chemical Society has announced the award of the Priestley medal, the highest honour in American chemistry, to Sir Ian Morris Heilbron, D.Sc., F.R.S., professor of organic chemistry in the University of London at the Imperial College of Science and Technology. Prof. Heilbron has in recent years worked on penicillin and the insecticide D.D.T.

During the first three months of this year a series of articles by Miss G. B. Carter and Miss Evelyn C. Pearce appeared in the *Nursing Mirror* under the title "Reconsideration of Nursing: Its Fundamentals, Purpose, and Place in the Community." These have now been reprinted as a pamphlet, and copies can be had for 6d. post free from the *Nursing Mirror*, Dorset House, Stamford Street, London, S.E.1.

The address of the Sheffield depot of the Regional Blood Transfusion Service is now Northfield Road, Crookes, Sheffield, 10. (Telephone No. Sheffield 63271.) This depot serves South Yorkshire, Derbyshire, Leicestershire, Lincolnshire, Northamptonshire, Nottinghamshire, and Rutland.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales, except for a decrease in whooping-cough 98, infectious diseases increased in prevalence, the rises being measles 407, acute pneumonia 103, scarlet fever 68, diphtheria 61, dysentery 24.

The decline in whooping-cough was due to a few counties; the largest falls were Hertfordshire 30, Staffordshire 28. The only counties with an appreciable change in the incidence of scarlet fever were Lancashire and Yorkshire West Riding, with increases of 49 and 40. A small increase in acute pneumonia was recorded in most areas. The largest rises in measles were Lancashire 168, London 78, Durham 43. The increase in diphtheria was contributed mainly by Yorkshire West Riding 18, London 14, Yorkshire East Riding 12, and Surrey 11. Diphtheria is most prevalent in Lancashire and Yorkshire West Riding, where almost one-third of the total cases were notified.

The chief centres of infection for dysentery were: Lancashire 86, Staffordshire 37, London 36, Middlesex 31, Essex 15, Warwickshire 15, Gloucestershire 10, Leicestershire 10, Glamorganshire 10.

In Scotland the chief changes in the incidence of infectious diseases were increases in measles 111 and acute primary pneumonia 21, and decreases in whooping-cough 34 and dysentery 13.

In contrast to the general trend, the notifications of dysentery rose from 5 to 16 in the city of Aberdeen. Although the notifications of diphtheria showed no change there was considerable local variation in incidence, and the western area had an increase from 79 to 92 cases.

In Eire there were diminutions in the incidence of primary pneumonia 27, whooping-cough 19, and diarrhoea and enteritis 13. The only increase of any size was diphtheria 8.

In Northern Ireland the notifications of scarlet fever fell by 9, and those for whooping-cough increased by 8.

Week Ending April 6

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,392, whooping-cough 2,109, diphtheria 463, measles 2,268, acute pneumonia 967, cerebrospinal fever 96, dysentery 294, paratyphoid fever 3, typhoid 3, smallpox 7. Deaths from influenza in the large towns numbered 47.

Corrigendum

In the "Epidemiological Notes" of April 13 (p. 593), relating to the week ending March 23, it was stated that Scotland had "an increase of 26 in cerebrospinal fever." It now appears that 18 cases of chicken-pox in Greenock were erroneously shown as cases of cerebrospinal fever. The total number of cases of cerebrospinal fever in Scotland for the week ending March 23 was therefore 40 and not 58, and the increase over the figures for the previous week was 8 and not 26.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended March 30.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

ANY QUESTIONS?

Essential Xanthomatosis

Q.—What is the underlying cause of the hypercholesterolaemia of essential xanthomatosis of the hypercholesterolaemic type?

A.—Essential xanthomatosis is taken to include xanthoma tuberosum multiplex and the Hand-Schüller-Christian syndrome. Characteristically, hypercholesterolaemia occurs in xanthoma tuberosum multiplex and not in the Hand-Schüller-Christian syndrome, and xanthoma tuberosum multiplex is more often familial, but cases occur with features of both syndromes. As hypercholesterolaemia is not an essential symptom, it seems likely that the primary disturbance is an increased formation and storage of cholesterol in the reticular cells, with a secondary spilling-over of cholesterol into the plasma in cases with hypercholesterolaemia.

Thorium X in Rheumatoid Arthritis

Q.—What is thorium X, and how should it be used in the treatment of rheumatoid arthritis?

A.—Thorium X is a mildly radio-active substance which soon loses its activity by disintegration. Its use in rheumatoid arthritis is empirical and no scientific or controlled studies have yet been made of this form of therapy. Two suggestions have been put forward to account for its value in this condition. First, it may be a "general stimulus to metabolism," causing an increase in the patient's resistance to the arthritic process. Secondly, it is suggested that the alpha rays emanating from the thorium X have a destructive effect on the growing scar tissue which is forming in the synovial membranes. Both these suggestions are vague and inconclusive.

Thorium X may be administered locally to the joint in the form of an ointment, or it may be given intravenously, but most commonly it is taken in solution by mouth in doses of 50 electrostatic units three times a day for three days. There is a danger of leucopenia which must be guarded against.

Inheritance of Retinitis Pigmentosa

Q.—In "Any Questions?" of Nov. 24, 1945 (p. 752), and again on Feb. 23, 1946 (p. 302), it is stated that there is no reason why persons suffering from retinitis pigmentosa should not have children. Could this be explained further? Some patients have long pedigrees of the disease and many affected relatives. Is it right to advocate the broadcasting in the population of such highly undesirable genes?

A.—The first sentence in the question is not quite correct. In both instances mentioned the individual family histories together with the known hereditary behaviour of the condition made it reasonably certain that a recessive gene is involved. It was because of this that it was stated that there was no sufficient argument against children, should the sufferers want them. Had inheritance been dominant (or sex-linked), which does occur sometimes, the genetic outlook would have been quite different and it would be most unwise to have children.

For practical purposes there are three simple types of inheritance: dominant, sex-linked, and recessive. A dominant gene is expressed even though the corresponding gene received from the other parent is normal. On the average, half the offspring of any affected person are themselves affected. Direct transmission of the trait is observed from parent to child.

Sex-linked traits, of which haemophilia is the classical example, depend upon genes carried on the X-chromosome, of which the female possesses two and the male only one. A carrier female, possessing one abnormal gene, is herself outwardly normal; but half her sons receive the abnormal gene on their single X-chromosomes and so are affected. An affected man who marries has normal children only, but all his daughters will be carriers. It can easily be seen, therefore, that in simple dominant inheritance the only problem is the affected person, the children of such people have a 50% chance of being similarly affected. With a sex-linked trait a woman who has already had an affected child has a one-in-four chance that any subsequent child will be affected. The sisters of a haemophiliac may or may not be carriers; the combined chance that any child will be affected is one in eight. A haemophiliac who marries will have normal children, but one-quarter of his grandchildren will be affected. It is clear, therefore, that in regard to these two modes of transmission some individuals run a risk which few sensible people would knowingly accept.

Recessive inheritance is quite different. Here both chromosomes of the pair concerned must carry the abnormal gene before the defect becomes manifest—i.e., one abnormal gene is received from each of the parents, who in the vast majority of instances will themselves be outwardly normal. A couple who have had one affected child run a one-in-four risk that any subsequent child will be abnormal also. The abnormal person himself carries two abnormal genes and so all his children will be carriers, but as in the great majority of instances he will marry someone who does not possess the gene, all his children will be normal. And so it may go on for many generations. The genetic prognosis is therefore excellent, with one proviso. The affected person (and his relatives) should not marry a cousin, because, of course, a cousin may well carry the very same abnormal gene. I saw a few weeks ago a patient suffering from retinitis pigmentosa, the first in her family group to do so. A normal sister had married a cousin and had had an affected child.

In all probability most of us carry at least one undesirable recessive gene, so that for every affected person there are many carriers. The reduction in the number of such genes by preventing the marriage of abnormals would be relatively trifling. If, therefore, we can be reasonably certain that a particular instance of retinitis pigmentosa is due to a recessive gene—and this is the rule—there is no reason to advise against marriage.

Efficient Stethoscope

Q.—Have any recent tests been made of the efficacy of various forms of stethoscope? As one gets on in years hearing becomes less acute, and one needs the most efficient instrument obtainable.

A.—It is the general experience that the open bell-shaped chestpiece used with a binaural stethoscope is the best combination for picking up low-pitched or rumbling murmurs—for example, those of mitral stenosis. On the other hand, the flat chestpiece with diaphragm (phonendoscope) is found by most observers to be best for hearing the high-pitched murmurs (often very soft) of aortic incompetence in the earliest stage. In general, for those hard of hearing, I would stress the value of well-fitting rubber ear connexions, and a rubber rim around the bell-shaped chestpiece, for the better exclusion of extraneous sounds, and thick rubber tubing for the same reason. For the auscultation of the lungs a physician hard of hearing will probably find the phonendoscope type of chestpiece more helpful.

Atropine in Labour

Q.—Ether anaesthesia being desired during the second stage, can atropine 1/100 gr. (0.65 mg.) be injected without affecting parturition?

A.—In laboratory experiments it has been shown that atropine can interfere with the action on uterine muscle of some drugs, such as acetylcholine and pilocarpine. Nevertheless, it does not block nerve impulses to the uterus, nor does it inhibit normal spontaneous uterine activity or interfere with the uterine response to posterior pituitary extract. In the past it was sometimes stated that atropine was contraindicated during labour because it might depress uterine contractions. This is not borne out by clinical experience, and A. W. Bourne and

J. H. Burn (*Journal*, July 19, 1930, p. 87) recorded the contractions of the human uterus during labour and noted that, if anything, the contractions were intensified rather than decreased after 1/100 gr. (0.65 mg.) atropine. Although the position is not clear (atropine is still recommended by some authorities in the treatment of spasmodic dysmenorrhoea) it may be stated that atropine in ordinary dosage can be given to the parturient woman without fear of materially disturbing uterine action.

Skimmed Milk for Children

Q.—Is skimmed milk suitable for feeding infants and older children? Is it correct to say that the only constituent it lacks as compared with cow's milk is fat; and that, but for the want of fat, it is equivalent to cow's milk in its content of mineral salts? The importation of skimmed milk into British Guiana at a reduced rate of customs duties in order to meet the scarcity of local cow's milk has given rise to varying opinions. The view that skimmed milk is suitable for infants was reported in the local press as having been expressed by a nutrition expert who visited this colony last year.

A.—This is a somewhat complicated question, and perhaps one should not attempt an answer without a knowledge of the local conditions in British Guiana and the choice of milk available. From a general point of view, it is fair to state that skimmed milk is not suitable for infants. Not only is the fat content reduced, but this naturally means that given in a strength in which the protein can be digested the calorie content of the milk mixture will be low. Moreover, it is generally accepted that the calcium of milk is in some physico-chemical relationship with the fat and, whether this be true or not, it does seem accepted that absorption of the calcium will depend upon fat intake. These remarks apply when milk is the sole source of food. In older children, on the other hand, it has been clearly shown that even skimmed milk is a valuable supplement to normal diet. It may be that the nutrition expert mentioned in the question had this in mind.

Thought, Emotion, and the Encephalogram

Q.—What are the effects of thought and of emotion upon the electroencephalogram?

A.—Attention of any kind will modify the records in the electroencephalogram. The usual dominant frequency of about 10 a second is inhibited by opening the eyes. This inhibition is not purely visual, it is the result of visual attention—so with any thought processes or emotional states which involve the patient's attention. Emotional states give rise to direct potential changes on the surface of the body, but these direct potential changes are not recorded in the electroencephalogram, which is so designed that it records only alternating and indirect current flow. In any case these direct potential drifts would not materially affect the electroencephalographic record.

Electric Shocks for Phlebitis

Q.—Five months ago, following confinement, a patient developed phlebitis in the left leg. Despite rest the leg remained painful and swelled every evening until one day, a week ago, when she received by accident a severe electric shock. From that minute the pain and swelling have ceased. Can you explain this?

A.—Persistent swelling of the leg indicates some impairment of the circulation; and, although vascular changes are sometimes found post mortem following fatal electric shocks, it is difficult to account for a sudden restoration of the circulation of the leg as a result of the accident described. It may be that the general upset occasioned by the shock has caused the patient to take more rest and thus minimized the swelling of the leg. A longer period of observation seems necessary before any conclusion as to the effect of the accident is justified.

Carbon Monoxide in a Bathroom

Q.—What is the simplest and most reliable test for the presence of carbon monoxide in a bathroom?

A.—Small amounts of carbon monoxide can be detected by passing the gas to be tested through a dilute solution of palladium chloride, or by exposing a filter paper soaked in this solution, when a darker colour is obtained owing to the presence

of metallic palladium. Other reducing gases, however, will give this reaction. The standard method of determining small amounts of carbon monoxide is based on the reduction of iodine pentoxide to iodine by CO. A portable apparatus based on this method is available in this country.

A portable instrument of a different type has been used in the U.S.A. A stream of air is drawn over a Hopcalite catalyst and the carbon monoxide is burnt; the heat thus produced is proportional to the amount of gas. The increase in temperature is detected by a thermocouple and recorded on a meter graduated in parts of CO per 10,000 of air. Such instruments must be calibrated frequently against a standard chemical method.

The detection of carbon monoxide in air and the subsequent analyses are definitely matters for an expert, who should be consulted if one had the slightest reason to suspect the presence of carbon monoxide in a bathroom.

Haemorrhagic Disease of the Newborn

Q.—A boy aged 7 developed haematemesis when 4 days old. At 5 weeks old, when put on to half-cream milk (he was bottle-fed), he developed scalp eczema, which subsequently spread to the flexures of the body. This now alternates with attacks of asthma. The father has hay-fever; and the mother's father, mother, and uncle had duodenal ulcers. The mother wonders whether the next child will be similarly affected.

A.—The three questions at issue are haemorrhagic disease of the newly born, allergy, and peptic ulcer. Tendencies to the two last are undoubtedly inherited and nothing dramatic can be done to prevent them, though breast-feeding is probably preferable to bottle-feeding for the allergic infant. Haemorrhagic disease of the newborn is not usually hereditary or familial; to prevent it, giving the mother 25 mg. of menaphthone or 50 mg. of acetomenaphthone at the beginning of labour, and the baby 5 mg. of menaphthone as soon as possible after birth, has been recommended.

Simmonds's Disease

Q.—What is the latest treatment for Simmonds's disease?

A.—In Simmonds's disease, as a result of anterior pituitary destruction, failure of function is met with in the gonads, thyroid, and adrenal glands. Theoretically, therefore, substitution therapy should comprise oestradiol (or stilboestrol, hexoestrol, or dienoestrol), progesterone, testosterone, thyroid, and desoxycortone or cortical extract, and these should be continued indefinitely. In practice, good results may be obtained with all of these, or with some of them. Thyroid should not be given, at any rate in large doses, in the early stages, as patients may prove intolerant, possibly because of the poor nutrition and glycogen depletion of the liver. Testosterone is indicated in the male, not only because of its effect on sex function, but because of its anabolic effect, resulting in an increase in appetite, gain in strength and in weight. The writer has also found it of great value in women, and the danger of hirsutism or acne seems to be much less in these patients than in other women. Methyl testosterone, 5 mg. t.d.s. by mouth, is partially effective, and may be supplemented by dienoestrol 0.3 mg. b.d., and ethisterone 10 mg. t.d.s., thus avoiding injections.

Stimulation of the gonads by gonadotrophins may be attempted, but patients may prove dangerously allergic, and in any case it is still only substitution therapy and must be continued. Fortunately, in partial Simmonds's disease there may well be, in the course of time, an appreciable degree of spontaneous recovery. Should pregnancy supervene, by any chance, the resulting hypertrophy of the undestroyed portion of the anterior pituitary gland will also tend to produce recovery. Pregnancy, however, is rare in Simmonds's disease of any severity.

Tuberculosis of the Breast

Q.—What is the best treatment for tuberculosis of the breast?

A.—Tuberculosis of the breast is uncommon. Infection may occur from the blood stream, which may convey the microbe from a pulmonary or other focus; sometimes, however, it appears to gain access through the nipple. The lesion may be subacute and fairly rapidly form a chronic abscess, and this may cause the formation of sinuses, which may betray the nature of the lesion. At other times the chronicity of the lesion may lead to fibrosis, which may very closely simulate

arcinoma. In nearly all cases the best treatment is complete removal of the breast. A possible exception is that case in which there is but a small lesion near the nipple, in such a case a local excision may first be tried.

Penicillin for Psoriasis

Q.—Is penicillin any use in psoriasis? If so what is the best way to give it?

A.—This question cannot be answered by a simple Yes or No. In those prone to this pattern of reaction psoriasis may be provoked by a variety of different causes at different times. The provocation may be an endocrine disturbance or may be climatic, it is often nervous but is sometimes toxic, from some infection or some infected focus. In the latter group of cases penicillin therapy parenterally is likely to be valuable for the particular attacks. No doubt a new line of therapy like penicillin will for a time bring relief through suggestion given either parenterally or by local application. I have little experience of its use in this manner, however.

Sterility following Mumps

Q.—An officer aged 27 complains of a heavy aching pain in his right testicle and groin. He developed mumps four months ago with a left orchitis. He lived ashore with his wife for a month with a resultant increase in the symptoms. His sexual potency and libido are not affected but he was worried about the possibility of sterility. The left testicle is atrophied and the right epididymis is slightly tender at times. He has worn a scrotal support for some time with no amelioration of his symptoms. I should appreciate advice as to treatment.

A.—It is stated that the left testicle is atrophied and that the right epididymis is occasionally tender. The word epididymitis is not used, and if no true infection of the epididymis has occurred there is no reason to believe that the patient is sterile. But if he is anxious about his condition—and it is not surprising that he should be—a specimen of semen should be examined. All that is required is to discover whether spermatozoa are present or not. No expert analysis is at the moment necessary. If the occasional tenderness and aching are due to congestion alternate sponging with warm and cold water, in addition to the wearing of a bandage often brings relief.

INCOME TAX

Demobilization—Car Expenses

T D's demobilization leave expired on Dec 31, 1945. He commenced work as an assistant in general practice on Dec 1. How is his assessment for the year to April 5, 1946, calculated? He has been using car A but intends to sell it and buy car B before the end of this month. What should he claim in that connection?

A.—T D will be assessed for the year to April 5, 1946 for nine months. Army pay (on the basis of the previous year if that is to his advantage) and for four months' civil earnings. For 1945-6 he should claim depreciation allowance on car A up to the date of sale, and on car B from the date of purchase—at 20% plus one fifth—and obsolescence allowance on car A—i.e. the cost price less the depreciation claimed on that car and less, also, the amount received for the car on sale. For 1946-7 he should claim the 20% "initial allowance" on car B—i.e. 20% on the cost price less the depreciation allowance claimed on that car for 1945-6, and also, of course, the depreciation allowance on the written-down value.

Sale of Car—"Balancing Charge"

C H has two cars, one of which "is valued at £12 for income tax purposes but is worth about £212 at market values." He wishes to replace it, but the new car will not be available until next August.

A.—If he sells the car on or after April 6, 1946, while carrying on the practice he will be liable to account for income tax on the excess of the amount received for it over the income tax value, subject to the fact that this "balancing charge" must not exceed the aggregate of the depreciation allowances made to him in respect of the old car. If he sells the car before April 6, 1946—which is the "appointed day" at which the Income Tax Act, 1945, comes into operation—he will not be liable to the "balancing charge."

Car Transactions

P M has a car ("M") which cost £130 in 1939, and on which he has received £111 in depreciation allowances. What will be the position if he sells it (a) before or (b) on or after April 6, 1946? A

Similar inquiry is made with regard to another car ("N") which has been depreciated to £275 and may be sold for £200.

A.—Car "M"—(a) If sold before April 6 no liability to a balancing charge will arise. (b) If sold on or after April 6 a balancing charge will be due, the amount being either the excess of the selling price over £19 (£130-£111) or £111, whichever is the less. Car "N"—If sold before April 6, P M will be entitled to the usual obsolescence allowance. If sold on or after April 6 he will be entitled to claim the excess of the depreciated value for income tax purposes (£275) over the selling price. (In this case the two allowances will appear to amount to the same thing.)

Lectures on a Non medical Subject

R is in practice as a consultant, but two or three times a year lectures for a fee on a non-medical subject. Should the fees be shown as income for tax purposes?

A.—Yes. It may be open to doubt whether they are chargeable under Schedule E but if not they appear to be caught by Case VI, Schedule D, as annual profits or gains, not charged by any other Schedule.

Change of Practices

J O sold a practice recently and is negotiating the purchase of a practice in another part of the country. With which tax office should he deal?

A.—As regards the former practice, the office which has hitherto dealt with his income tax liability, as regards the new practice—it is in fact acquired—the office dealing with that locality.

Colonial Medical Service

L L arrived in England in December, 1945, for a course of study. Part of his salary is paid to his wife abroad, the balance is paid to him here.

A.—As L L has come to the United Kingdom for a temporary purpose and not with a view to establishing a residence here, he will not be liable to British income tax if he is not in the country for six months of the financial year. He will not be liable for 1945-6, but will be liable for 1946-7 if his stay here lasts beyond Oct. 5, 1947. If that occurs he will be liable on the amount of pay received here, less the usual personal allowances and less some allowance for income tax paid on the same income in the colony.

LETTERS, NOTES, ETC.

Keeping Properties of Serum and Plasma

Dr K S RANGASWAMY writes from New Delhi. The statement that "human citrated plasma in liquid form should not be stored unless frozen in the solid state" (Jan. 26, p. 152) is rather dogmatic and may create an impression that the use of plasma stored in liquid form is dangerous. In my experience processed plasma stored in the liquid state is a perfectly safe product to use for resuscitation and maintaining a lost blood volume. At the Madras Blood Bank, the King Institute of Preventive Medicine, Guindy, we have prepared and issued during the last three years only liquid plasma processed according to the alkali- CO_2 neutralization technique described by Blash and Wherry. In 1943 and 1944 most of the plasma prepared had been held in storage at 42° F (5.5° C) to meet any possible emergency. The safe time limit for the storage of plasma was then not known, though it was frequently mentioned in the literature that fluid plasma could be stored for "several months." After careful clinical trials the time limit was extended gradually from three months to one year. Some hundreds of transfusions have been given in the Madras hospitals with plasma stored for about one year, and, in some cases, for about eighteen months. From this experience we have fixed that the safe storage period for wet plasma should not ordinarily exceed twelve months. In a paper read before the Madras Medical Association on March 9, 1944, I gave the results of clinical trials with wet plasma, analysing the data of 105 transfusion cases of which the blood bank had complete records. The plasma had been used for the treatment of post-operative shock in 77 cases, injuries including gunshot 10, burns 17, and shock after spinal anaesthesia 1. Of these cases 7 developed a rigor, 4 had a rise of temperature, while 1 had uricæmia after transfusion of plasma. The results were excellent: life undoubtedly saved in 19, good in 46, improvement followed by death of the patient in 25, and no improvement in 15. A surgeon who had used large amounts of fluid plasma summed up his impression by reporting "The use of plasma saved a number of lives. Many of them would not have recovered but for the plasma."

Among those who were not benefited by plasma transfusion were many patients in an advanced state of shock who could not be expected to recover under any treatment to give a few instances, cases of perforated gastric and duodenal ulcers, traumatic rupture of intestines, strangulated hernia of three days' duration, etc. One transfusion report contains a remark which gives an idea of the type of cases falling in these groups: "The [blood] pressure never

rose in spite of giving plasma in a continuous stream by the open method," a typical example of the terminal stage of shock. In some cases the plasma was given too late, while in others the plasma was given either too slowly or in insufficient amount to have any real effect or was stopped too soon so that the initial improvement was not maintained. In two cases it was suggested that the plasma transfusion was followed by ill-effects. These have been investigated. The first was a patient with hypertension in whom plasma transfusion was commenced after the B.P. had fallen from 160/80 to 90/76 during an operation for excision of elephantoid scrotum. The plasma transfusion was continued at the rate of 70 drops a minute, 1,000 ml. being given in four hours. The B.P. continued to fall and the patient died. It was obviously a case of inadequate speed and inadequate volume. The other was a patient on whom a hemicolectomy had been done for ileo-caecal tuberculosis. When the plasma transfusion was started the patient's condition was "bad." The B.P. was 104/60 and pulse rate 102; 500 ml. of plasma was given in one hour, when the patient's condition became "worse," with B.P. 90/58 and pulse rate 136. An hour and a half later an intravenous infusion of normal saline was started and the patient improved, the B.P. rising to 118/68. I venture to suggest, from my experience of two other similar cases in which a saline infusion restored the B.P., which had fallen apparently due to transfusion of plasma, that these are cases of dehydration which fare badly when plasma is given without concomitant administration of saline solution. Since March, 1944, some hundreds more transfusions of stored fluid plasma have been given with very favourable, and in some instances spectacular, results. I am unable to analyse these results as I have no access to the records, which are in far-off Madras.

I have been constrained to make the above observations at some length because processed human citrated plasma and serum stored in the fluid state are in general use all over India except in one or two centres where facilities for drying plasma/serum exist, and any impression that the use of such products is fraught with danger would have disastrous consequences in India and would retard the progress of transfusion in this country. Besides, facilities for storing plasma in the frozen state are equally lacking in India. Experience has shown that properly processed plasma can safely be used after storage at low temperature even in the Tropics.

Are the People More Healthy?

Surg. Lieut.-Cmdr. G. H. C. ST. G. GRIFFITHS, R.N.V.R., writes: Your article on this intriguing subject (March 2, p. 318) touched inclusively on "health," discerned from rather a limited aspect—e.g., coryza, influenza, rheumatism, tuberculosis, and the mortality rate. It did not take into consideration that colds, 'flu, and even rheumatism, ought to be more epidemic one year or season, or the climate was more humid or exacting. Even on peacetime food abundance it must be admitted that epidemics of these diseases are more prevalent in one year than another, or the season is wetter and the rainfall greater, so that food, or the lack of it, may not have contributed to the figures stated in the article in question. Those responsible for the dieting of the nation naturally had to use propaganda of a cheering type, to encourage the public to undertake their long and arduous sacrifices and to endure their lot in going without many valuable foods, such as cheese, cream, butter, eggs, fine bread, meat, and a host of other peacetime foods. Substitutions, such as synthetic jams, powdered egg, peanut butter, varieties of margarine or "honey," were all served to the public in turn to eke out the monotonous and irksome diet that had to be faced, and unfortunately still has to be, owing to the alleged world shortage. However, all these sacrifices led to a "something" that we, as a nation, had not known previously: a general lassitude, languor, lack of energy and driving power; a lack of quick recuperative power to 100%, if ever attained, after some trifling illness. There seemed to be many individuals, men and women, suffering from varying slight grades of anaemia. Fractures, too, through deficient calcium, were more numerous. Accidents causing fractures on the football field were in excess of normal. These fractures often showed grave osteoporosis and decalcification of the bones, the bones appearing under x rays to be little more than fibrous tissues. Skin diseases such as acne pustulosa, furuncles, bullous pemphigus, and carbuncles seemed much more common, due to lack of fresh meat, fruit, and similar foods. Teeth also were not spared, owing to our lack of milk, cream, and butter. The reference to the mortality rate hardly holds good. Millions of people can be more or less starved to a certain extent without reaching the condition of those in Belsen Camp. No grievous epidemic, either, overtook this country, as in 1918, to decimate its inhabitants.

Schizophrenia and War Service

Mr. J. H. WOOD, Secretary, Pensions Department, the British Legion (Scotland) writes: With reference to the question and answer (March 16, p. 419) regarding the Ministry of Pensions and the above disease, first of all, may I point out that the Pensions Appeal Tribunals are independent and not run by the Ministry, and they consist of a lawyer, a doctor, and an ex-Service man. Although in the

case quoted there was no pre-Service history of the disease and the family history was good, I am afraid that the Ministry of Pensions would only admit that the schizophrenia was aggravated or, in other words, made worse by his service in the Navy, but would not admit that it was attributable thereto, their view being that no case of schizophrenia can be due to war service as in every case there is a constitutional predisposition. At the risk of incurring the wrath of many psychiatrists, but not all, I may say that the British Legion disagrees entirely with this point of view, and holds that in cases such as the above the disability can be fairly said to be attributable to war service. Here it is worth noting that in the old Royal Warrant the words "directly attributable" were used, and we would admit in that case that where a predisposition exists it could not be "directly attributable." However, in the present Royal Warrant the word "attributable" appears by itself, and therefore, if a man has a good personal and family history and breaks down under Service stress, the obvious conclusion to be drawn is that the psychosis is attributable to war service. It is also worth noting that Brig. G. W. B. James, in the *Journal* of Nov. 3, 1945 (p. 620), says that in some cases schizophrenia can be fairly said to be the direct result of war service. If only we could alter this attitude of mind in the Ministry and on the Pensions Appeal Tribunals, who, I am sorry to say, uphold the Ministry in their misinterpretation of the word "attributable," the Legion would be a lot happier.

Intravenous Protein Hydrolysates

Dr. A. NEUBERGER, Secretary of the Protein Requirements Committee of the Medical Research Council, writes: Dr. H. E. Magee states that "British preparations for intravenous use are made by hydrolysing casein with sulphuric acid." This is not the case. All preparations which have been tested in this country under the auspices of the Protein Requirements Committee of the Medical Research Council have been prepared by enzymic hydrolysis. One particular preparation made with acid and which had been supplemented with tryptophan has been used in a small number of cases abroad. Dr. Magee also states that "a few repatriated prisoners of war were treated with protein hydrolysates in England in 1945 with some but not spectacular success. Thrombosis of injected veins occurred in every case." It must be pointed out that in the clinical tests carried out under the auspices of our committee thrombosis, though undesirably frequent, was not a regular feature, as implied by Dr. Magee. Thrombosis has also been occasionally observed when American preparations were used. It is clear that further work both on the production of protein hydrolysates and on the clinical administration and indications is required before this method of intravenous alimentation can be recommended for general clinical use.

Height of Water-closet Seats

Fl. Lieut. R. S. HENDERSON, R.A.F.V.R., writes: Surely there is little doubt that the ideal posture for defaecation is a crouching one, with spine, hip-joints, and knee-joints fully flexed, the feet apart, and the anal orifice as near the ground as possible. Most animals may be observed to find this natural and effective. Campers, passing their motions into prepared holes in the ground, know it to be ideal. Now lavatory seats, as at present designed, are never less than 18 in. to 2 ft. (45 to 60 cm.) off the ground. At a time in history when we are expecting almost at any hour the appearance all over the country of new houses, it seems that builders generally might be encouraged to lower the height of their lavatory seats from the ground to a maximum of 12 in. (30 cm.). Quite apart from the saving of material involved, the nation as a whole might thus find itself pleasantly less constipated—with incalculable benefit, no doubt, to the rest of the world.

Blood Transfusion Apparatus

Mrs. A. D. HEDGES, secretary of the Durban Blood Transfusion Service, writes from Addington Hospital, Durban, South Africa: The Durban Blood Transfusion Service has started a small museum and we would like readers of the *British Medical Journal* who have any discarded pieces of blood transfusion apparatus, for which they have no further use, to consider sending them to us.

Corrections

In the report of the Royal Society of Medicine discussion of vascular injuries of warfare (April 6, p. 540) "Mr. Mayer" should read "Mr. B. C. Maybury." We apologize for the error.

Dr. STEPHEN D. STURTON wishes to correct a misprint in his letter on "Deck Ankles" and "Travellers' Oedema" published in the *Journal* of April 13. The third sentence of the second paragraph should read: "By the morning of July 12 out of 314 prisoners 24 of us were suffering from this condition."

Mr. F. G. ST. CLAIR STRANGE, F.R.C.S. (Ministry of Pensions Hospital, Dunston Hill, Gateshead, Co. Durham) is seeking back numbers of the *British Journal of Surgery*. The copies he wants are (up to twelve in number) of the July, 1945, issue, Vol. XXXIII, No. 129.

RECENT ADVANCES IN THE PHYSIOLOGY OF VISION

By

H. HARTRIDGE, M.D., Sc.D., F.R.S.

Professor of Physiology, St. Bartholomew's Hospital Medical College

Section I: Measurements of the Living Human Eye by Means of X Rays

Rushton (1938) appears to have been the first to use x rays for making measurements of the living human eye. He measured its antero-posterior diameter. Goldmann and Hagen (1942) employed Rushton's method, and themselves measured the same diameter in the case of 10 emmetropes, 7 myopes, and 1 hypermetrope. They also elaborated the method in a very ingenious way by causing two pencils of x rays to strike the retina near the fovea; this enabled them to determine the more important optical constants of the eye. This method—together with some of the results which they obtained—will be reviewed in this section. Recently Sorsby and O'Connor (1945) have also elaborated the method so as to measure not only the antero-posterior diameter but the transverse and vertical diameters as well. Their results will also be reviewed here.

The Methods of Goldmann and Hagen

Knowledge of the optical constants of the eye finds many applications, both practical and theoretical. For this reason several attempts have been made to determine these constants both for the normal human eye and for myopes and hypermetropes. The older methods were laborious and their accuracy was open to doubt. Recently a more reliable method has been developed by Goldmann and Hagen by the use of x rays. So far, two properties of the eye have been determined by them—the length of the eyeball and the total refraction of its lens-system. The first of these is measured as follows: A beam of x rays is passed through a slit-shaped aperture in a stout metal plate. The narrow ray thus produced is caused to fall on the observer's dark-adapted eye at right angles to its optic axis. A ring of light is seen concentric with the fovea. As the beam is moved towards the back of the eye this ring of light gets smaller and smaller until it shrinks to a point. The beam now coincides with the most posterior part of the retina. The whole instrument is then moved forwards until the beam illuminates the anterior part of the cornea, and the movement necessary to do this is carefully measured. Since x rays are not deflected by living tissues the length of the eyeball is accurately determined in this manner.

The total refraction of the eye is now ascertained by the following technique: Two narrow beams of x rays, about 5 mm apart, are projected in at the front of the eye just below the line of sight. The observer sees two bright images apparently projected on to a screen which has been placed in front of him. Two narrow beams of light are projected by an optical lantern on to this same screen and the beams are adjusted until they coincide with the x-ray images. The exact distance of the screen from the observer is carefully measured, so also are the distances between the two lantern beams. The following formula is now used:

Total refraction in dioptres

$$= \frac{1000 \times \text{distance between lantern beams}}{\text{Screen distance} \times \text{distance between x rays}}$$

In the following table the results obtained by Goldmann and Hagen are compared with those of two observers—Tscherning and Gullstrand—who employed the older methods referred to above.

	Goldmann and Hagen	Tscherning	Gullstrand
Length of eyeball	23.40 mm	24.75 mm	24.00 mm
Total refraction	59.22 D	58.33 D	58.64 D
Nodal distance	16.83 mm	17.13 mm	17.05 mm
Posterior focal distance	22.53 mm	22.83 mm	22.78 mm

It will be seen that there is remarkable agreement between the results obtained by the three observers. The mean values are as follows: Length of eyeball=24.05 mm.; total refraction=58.75 D., nodal distance (the distance between the retina and the posterior nodal point)=17.02 mm.; the posterior focal distance=22.73 mm. In every case the mean values are very close to those given by Gullstrand.

The Methods of Sorsby and O'Connor

These observers measured the three principal diameters of the living human eye. After 15 minutes' dark-adaptation the observer's head is clamped. A slit-shaped beam of x rays is now adjusted until it is tangential to the retina first on one side and then on the other. The two positions of the beams are recorded on a photographic film introduced in front of the eyes. The following details of some cases were kindly sent to me by the authors.

Case	X-ray Measurements (mm.)			Refraction	
	Transverse	Vertical	Axial	Vertical	Horizontal
1	21.5	20.5	22.0	0	0
2	23.5	23.0	25.0	-1	+2
3	24.0	24.5	25.0	-3.5	-2
4	23.5	24.0	23.0	-1.0	-1.5
5	24.5	25.0	23.0	-16.0	-14.5
6	24.5	23.5	24.5	0	-0.5

It is interesting that the one case of high myopia shows a long axis. Prof. Sorsby has informed me privately that a second case of myopia was found to have an eyeball of normal length. This method will clearly be of great value in locating foreign bodies opaque to x rays in the eye.

Section II: The Micro-electrode Experiments

Of all the advances made in recent years in the physiology of vision possibly the least expected, and the most far-reaching, are the researches of Granit (1943) on the mammalian retina. The three-colour theory of Thomas Young was so well known, and seemed to be so firmly established as the result of the work of Wright, his co-workers, and many others, that any discovery contrary to it appeared to be most unlikely. It had been known for some time that there were defects in the three-colour theory;

but that the theory could be wrong in essential features was certainly not expected.

The theory apparently has had its day; but during its life it has served a very useful purpose, for it has been the inspiration of much research work and has formed the basis of a convenient way of designating colours. It has also provided a good classification for colour-blind persons and has indicated practical methods of colour photography and cinematography. It should be pointed out that, although the three-colour theory is now in peril, none of the practical applications which have developed from it is in a similar plight. We can still enjoy technicolour or say that a particular patient is red-blind.

Granit's experiments depend on the well-known principle that when a sensory nerve conducts impulses it undergoes changes of electrical potential. The retina of an animal is exposed and a very fine electrode is placed in contact with a single fibre of the optic nerve. This electrode is then connected to a high-gain amplifier and loud-speaker. When the rod, or cone, sense organ connected with the nerve fibre in contact with the micro-electrode is affected by light, changes in potential will be set up in it during conduction, and these will be shown by clicks from the loud-speaker. The stronger the light the more frequent the nerve impulses and the more numerous the clicks. As would be expected, in order to make connexion with a single optic-nerve fibre a very fine micro-electrode indeed must be used. Lastly, the experimenter himself must possess great skill and an aptitude for this kind of work. This is briefly the technique employed by Prof. Granit. Actually the light is not varied in intensity, but in wave-length, in order to determine the response curve of the paracular retinal receptor under investigation. When the curve for one receptor has been determined the electrode is shifted slightly so as to make contact with a neighbouring nerve fibre, which connects to another receptor. The taking of the response curve is then repeated.

When a large number of response curves have been obtained in this way they are sorted into groups, and usually as many as eight types of receptor are found to be present. Type I, which has a broad response curve, is stimulated by nearly all parts of the spectrum. This Granit calls a "dominator." The remaining seven types, all of which have narrow response curves, are stimulated by a part of the spectrum only. These Granit calls "modulators." There is one type of modulator for the orange, another for the yellow, three types for the different shades of green, and two for the blue. These results have been obtained on experimental mammals. If man were to be similarly tested it is probable that much the same result would be obtained in his case. Possible methods of testing this point are being investigated. The total number of types of receptor may well differ in man from other mammals, and their response curves may be different also. Thus from observations in man's colour sense one would expect there to be a type of receptor for the red part of the spectrum in addition to those that have been mentioned above.

While these points of detail remain undecided a temporary name is required to specify this theory of vision. The term "polychromatic" would seem to be not inappropriate. Suppose this theory to be substantiated for man as a result of further research, should we be better off than before? The answer to this question would appear to be "yes," for we could explain on this theory many visual phenomena which the old trichromatic theory is unable to do. Moreover, we should have a more precise method of classifying colour-blind patients.

Section III: Visual Acuity using Lights of Different Colour

König (1894) and Roaf (1930) found that when the acuity of the eye was determined, using lights of different colour, the results for blue lights were less good than those for other colours. Roaf explained these observations by assuming that rods are used in vision when blue light is falling on the retina. Since there is a rod-free area at the centre of the fovea this will account for the poor acuity by blue light. Shlaer (1937) advanced the hypothesis that the acuity of the eye is limited by the size of the pupil when it has a diameter of 2.3 mm. or less because, as is well known, diffraction effects occur at such a pupillary opening. If Shlaer's hypothesis were correct there should be better acuity by yellow light than by red light, better

acuity by green light than by yellow light, and better acuity by blue light than by green light. Shlaer, Smith, and Chase (1941) investigated the acuity of the eye, using lights of different colour, but their results did not confirm the above hypothesis. It is true that there was some slight improvement on passing from red light, through yellow light, to green light, but after that there was a marked deterioration. With a Landolt C test object there was little difference of acuity when lights of different colour were compared with white light.

Last year I investigated the effects of coloured lights, using certain letters as my test objects, and this year I repeated the experiments with Landolt's C test. In none of my tests was there any well-marked difference between white lights and coloured lights. The results of Shlaer and his co-workers, and myself, are summarized in the table below:

Observers	Visual Acuities using Lights of Different Colour				
	Test Objects	White	Red	Yellow-green	Blue
Shlaer <i>et al.</i>	Grating	1	0.91	1.02	1.00
	Landolt's C	1	1.00	—	1.00
	Letters	1	0.82	0.96	0.71
Hartridge	Landolt's C	1	0.86	0.99	0.91
	Mean	1	0.90	0.99	0.92

Great care was taken in my experiments to see that the coloured lights were of the same visual intensity. This is important because visual acuity improves as the brightness of the light increases. The conclusion that the acuity of the eye is substantially the same for white and for coloured lights not only fails to confirm the two hypotheses mentioned above but also puts great difficulties in the way of the usual form of the three-colour theory of Thomas Young, according to which certain retinal cones respond to red, others respond to green, while a third set respond to blue.

If these are all distributed according to a regular plan one would expect the acuity of the eye for red, green, or blue to be very definitely less than that for white, as a larger test object would have to be used with the former in order that discrimination may occur—because of the considerable distance between a photoreceptor of one particular kind and the next one to it of the same kind. On the contrary, when white light is in use all photoreceptors respond, irrespective of their peculiarities. In order to account for these results on visual acuity, and certain other properties of the eye which are at variance with the usual three-colour theory, an alternative theory called the cluster hypothesis has been advanced. This is dealt with in the next section.

Section IV: The Cluster Hypothesis

According to this hypothesis, when structures approximate similar in size are distributed in a random manner those of similar property tend to form small clusters or aggregates consisting almost exclusively of structures of one kind. Thus according to this hypothesis, if a small quantity of starch divided into three roughly equal parts and the first part be stained red, the second stained green, and the third stained blue—if then these three parts are intimately mixed together and examined, clusters of red grains should be found in one place, clusters of green grains in another place, and clusters of blue grains in a third place. These clusters are easily seen if a piece of Lumière screen, prepared for colour photography, be examined under a low-power microscope.

According to the cluster hypothesis, the retinal sense-organs are arranged in a random manner and accordingly form clusters in one place there is a collection of red receptors; in another place a collection of green receptors; while in a third place there is a collection of blue receptors. When high acuity is wanted with red light a red cluster is used for purposes of observation; when the light is green it is a green cluster which is employed; and when the light is blue a blue cluster is brought into play. With white light, on the contrary, it is either a green cluster or a mixed cluster which is employed.

This arrangement of the retinal receptors into clusters accounts for the high acuity of the eye using lights of different colour. It also accounts in a satisfactory manner for other

properties of vision which up to now have been difficult to explain. One of these is the retinal direction effect of Stiles and Rawford. This aspect of the cluster hypothesis is to be dealt with in detail elsewhere.

Using as test objects extremely small disks, it has been possible to identify the position of some of the clusters near the centre of a human fovea. This matter is also to be considered in detail elsewhere.

Section V: The Antichromatic Response

Physiologists have long been puzzled by one property of the lens system of the eye—namely, the absence of colour from the images of colourless objects which it produces on the retina. A lens employed for photographic, microscopic, or similar purposes has to be achromatized by the use of convex crown glass lenses in conjunction with concave flint-glass ones. Such combinations of lenses bring light of different colours to the same focus. Such is not the case if a single lens, either of flint glass or of crown glass, is used by itself. Thus a convex lens brings the violet rays to a focus first, then follow in order the blue, the blue green, the green, the yellow, the orange, and lastly furthest from the lens the red. It has been shown by experiment that this is the order of the colours in the case of the eye. It has also been shown that it is the yellow-green rays that are sharply focused on the retina under normal circumstances. The consequence is that the orange and red rays which have not yet come to a focus, form blurs on the retina, so also do the violet, blue, blue green, and green rays, because having come to a focus, they diverge again before they reach the retina. The image on the retina of a small bright white light on a black background will thus take the form of a yellow spot of high intensity surrounded by a blue halo or fringe which consists of the unfocused colours. So far theory and observation have been in close agreement, but now they differ to a startling extent. For when the observer looks at a small bright light he does not see either the yellow spot or the blue fringe. What he sees is the white light unaccompanied by any colours. Similarly in the case of other objects, both black and white, when these are looked at, coloured fringes—yellow or blue—should be visible owing to the chromatic aberration of the eye. But observation shows that in fact all such effects are conspicuously absent. In the past numerous hypotheses have been advanced to explain the absence of chromatic fringes from vision, but none of these has been able to stand critical examination. The correct explanation has been advanced recently—namely, that the spurious colours of chromatic aberration are eliminated by a nervous process, which has been called the antichromatic response.

A grating test object is prepared consisting of two parts—the upper part of alternate black and white stripes, the lower part of similar blue and yellow ones. The black and blue stripes are in the same straight line, so also are the white and yellow ones. An image of this test object is produced by a simple convex lens of about the same focal length as the eye, and this image is examined by a low-power microscope which magnifies 80 to 100 diameters. In consequence the observer sees an enlarged picture of the test object. He finds that both parts appear blue and yellow—one part because these are the actual colours which are present and the other part because of the colour effects produced by the chromatic aberration of the lens. Unfortunately, no satisfactory method has so far been devised of repeating this test using the lens system of the eye, but there is no reason to doubt if this were done, that a similar result would be obtained. A further test is now performed with the test object a few feet from the observer, when he looks directly at it he sees it in its natural colours—one part in black and white, the other part in yellow and blue. The distance between the test object and the observer is now increased until a position is reached at which both parts of the test object appear black and white. When this is the case not only have the colours produced by chromatic aberration been eliminated but real colours as well.

If this experiment be now repeated, using blue test objects alone or yellow test objects alone, a similar result is observed, the blue is replaced by dark grey or black, while the yellow is replaced by white. Further details will be given elsewhere, together with the reasons for concluding that somewhere on the

pathways between the retina and the brain there are situated nerve centres, one of which deals with blue while the other deals with yellow; and that these two in conjunction have the function of eliminating from vision the spurious colours produced by the chromatic aberration of the eye.

THE PATHOGENICITY OF PENICILLIN- INSENSITIVE INFECTION

BY

H. R. S. HARLEY, M.B., M.S., F.R.C.S.
Lieut.-Col., I.M.S.

J. A. BATY, O.B.E., M.B., Ch.B., F.R.C.S. Ed.
Lieut.-Col. R.A.M.C.

AND

J. H. BOWIE, M.B., Ch.B.
Major, I.M.S.

In countries where animal, insect, and human life are closely associated it is not surprising that Gram negative infection fails to follow the rules as laid down by workers in Europe. It is the object of this paper to show that, in the East at any rate, infection of wounds with penicillin insensitive organisms is common and must be taken seriously, and it is hoped that further interest will be stimulated in this important subject. Our observations are confined to infection with the three Gram-negative organisms—*Bact. coli*, *Ps. pyocyanea*, and the *Proteus* group—on the one hand, and penicillin insensitive strains of *Staph. aureus* on the other.

Two groups of workers, the one situated in the forward base areas in A.L.F.S.E.A. and the other at the rear base in India, both came to the same conclusion, quite independently, that infection with any of the penicillin insensitive organisms mentioned above can result in a serious threat to life and limb. Papers continue to appear stating that the penicillin insensitive Gram-negative organisms have no tendency to give rise to septicaemia or spreading infection, and that their action probably remains local in fact, that in wounds they are essentially saprophytic.

The Gram-negative Bacilli

Before the advent of penicillin the organisms which were responsible for most of the devastation wrought by sepsis were the *Staph. aureus* and the *Str. pyogenes*. The Gram negative bacilli and other microbes were considered to play a very subordinate part, even now they are held to be of very secondary importance by most European workers. Miles, writing in the *Lancet* of June 24, 1944, stated: "The two outstanding causes of severe wound infection are *Staph. aureus* and *Str. pyogenes*, the one being present in up to 100%, and the other in up to 70% of infected wounds." Elsewhere in that paper the same author refers to the rarity of "blue pus" in wounds. Hendry, Gledhill, and Price, writing in the *Lancet* (1945 1, 618), refer to *Ps. pyocyanea* and *Bact. coli* as non pyogenic. Our experience in the East has been far less happy.

With the control of *Str. pyogenes* and sensitive strains of *Staph. aureus* by penicillin, *Bact. coli*, *Ps. pyocyanea*, and the *Proteus* group of organisms have been left free to demonstrate their pathogenic potentialities and to show that in certain circumstances they are capable of behaving in a manner which is anything but saprophytic. In the East *Bact. coli*, *Ps. pyocyanea*, and the *Proteus* group now represent the "Big Three" so far as wound infection is concerned, and workers recently arriving from Europe should be made fully aware both of their malignant nature and of their ubiquity. These three, together with penicillin insensitive strains of *Staph. aureus*, are now the

cause of a major proportion both of fulminating and of prolonged low-grade infection in bone following war wounds. Lieut.-Col. Moffat, adviser in oto-rhino-laryngology for A.L.F.S.E.A., carried out investigations on antral, ear, and throat infections, and was impressed by the very high incidence of *Bact. coli* and *Ps. pyocyanea*. He expressed the opinion that, especially in the pre- and post-monsoon periods, the air and dust must be highly charged with these organisms. It is thus not surprising that their incidence in wounds is abnormally high. Of 86 wounds associated with late-infected compound fractures seen at the rear-base level, one or other of the three Gram-negative organisms was present in no fewer than 67.4% on admission. In a series of 65 late-infected compound fractures *Proteus* group was present in 53.8%, *Ps. pyocyanea* in 20%, and the *coli-aerogenes* group in 10.7%. In the forward areas *Bact. coli* was relatively more and *Proteus* group less common.

It was soon appreciated that when using penicillin tubes for the local instillation of penicillin into wounds every possible precaution was frequently ineffective in preventing the appearance of Gram-negative infection. Such infection occurred in 50% of our cases, and was often responsible for the breaking down of wounds. Break-down was liable to occur even in soft-tissue wounds when the secondary invader was a penicillinase-producing strain of *Bact. coli*. Pus associated with the presence of *Ps. pyocyanea* or *Proteus* group, on the other hand, could usually escape or be expressed from the depths of a soft-tissue wound, which then healed in a satisfactory manner. In the case of soft-tissue wounds infected with penicillin-insensitive organisms there was no instance of severe toxæmia following suture under local penicillin. In this respect our observations coincided with those of workers in Europe, but when closure of femoral fractures was undertaken it soon became apparent that Gram-negative infection was anything but innocuous.

Since in the compound femoral fracture it is notoriously difficult to perform a complete primary wound excision, it is not surprising that it is in this type of injury that both penicillin-sensitive and penicillin-insensitive organisms persist after the primary operation. It was amongst the compound femoral fractures that most of the complications associated with Gram-negative infection were encountered. When attempts were made to carry out delayed primary suture on or about the fifth day after wounding it was appreciated that infection, uncontrolled by both penicillin and the sulphonamides, was being locked up in the wound. Three cases in succession forcibly demonstrated that delayed primary suture of a compound femoral fracture was not a wise procedure under the conditions prevailing east of the Brahmaputra. The following is a brief account of the first of these, in none of which were Gram-positive organisms found, except where stated.

A patient with a grossly shattered lower third of the femur associated with a lesion of the sciatic nerve was sutured on the fifth day after wounding. Penicillin was administered both systemically and locally via tubes distributed in and around the site of fracture. A few days after suture there was a profuse discharge from the wound. *Bact. coli* was isolated from the pus. Persistence of a swinging pyrexia and the appearance of toxæmia demonstrated that evacuation of the Gram-negative pus along the tubes was inadequate, and a large collection was accordingly drained posteriorly by a free incision extending to the proximal limits of the cavity. This operation led to a temporary improvement, but within a few days, in spite of a full course of sulphathiazole, it became evident that unless some radical procedure was adopted the patient would lose his life. Blood transfusion allowed amputation to be performed at the site of fracture, the flaps being left open. At operation it was noted that infection was well established in the bone distal to the site of fracture and also amongst the numerous fragments that were present. There was no undrained collection of pus. The patient was apyrexial within a week of amputation and toxæmia rapidly abated.

In the next two cases an effort was made to forestall the possible collection of Gram-negative pus by the provision of prophylactic posterior drainage. At the time of delayed primary suture a short wide-bore drainage-tube was inserted into the most dependent and proximal part of the haematoma via a posterior stab incision. Systemic penicillin therapy was combined with local instillations. For half an hour before each instillation the clamp was released from the sump drain to allow the escape of any pus which had collected. In one case the initial bacteriological examination had revealed *Str. viridans*, and in the other *Staph. aureus*. In both the wounds Gram-negative infection appeared within the first week, and

there seems little doubt that it gained access through either the penicillin tubes or the sump drain. Both patients became extremely ill, and in both the infecting microbe was *Bact. coli*. Opening up of the original wounds to give free drainage, combined with the use of sulphathiazole, failed to prevent extension of infection along the thigh, and this was accompanied by high swinging pyrexia and marked constitutional disturbance. It became necessary to make further proximal incisions as localization of pus occurred. Only after many weeks did *Bact. coli* disappear, leaving the patients with all the effects of prolonged and profound toxæmia.

The experience gained from the preceding three cases led to the abandonment of delayed primary suture for compound fractures of the femur. The safer procedure of secondary suture with drainage after bacteriological examination was adopted instead. An initial wound swab was taken when the case arrived between three and five days after wounding, but no attempt at suture was made. Local procedures were limited to the removal of foreign bodies, correction of displacement, and, if necessary, more free exposure of the fracture site to ensure adequate drainage. The fracture was appropriately immobilized after the application of an occlusive dressing. Systemic penicillin was combined with the giving or completion of a 40-g. course of sulphathiazole. Although there were exceptions under this treatment, to be referred to later, it was the rule to find that the patient became apyrexial within ten days, and that both local and general conditions remained, or became, satisfactory. It was found that many of the wounds became free of pathogens and that secondary suture performed at this stage was followed by a smooth post-operative course. At the time of secondary suture the fractured bone ends were no longer visible in the depths of the wound, and closure of the latter was more on a par with closure of a soft-tissue injury. Even if the initial wound swab yields a penicillin-insensitive organism, free drainage combined with sulphathiazole should limit the spread of infection at this stage. Secondary suture with drainage performed on the tenth or twelfth day, when tissue planes are already sealed off and local adjustments have occurred, should give rise to no anxiety provided the bone is not involved.

The following six case summaries should provide strong evidence that infection with penicillin-insensitive Gram-negative organisms can produce illness of the utmost gravity in compound fractures of the femur, both recent and old. In addition to these many other cases of severe or prolonged illness have been seen after infection of compound fractures with Gram-negative bacilli.

Case I

This patient was admitted on Feb. 4, 1945, four days after sustaining shell wounds which had caused soft-tissue injuries on the left thigh and a compound fracture of the right femur. In the soft-tissue wound, from which a profuse growth of *Bact. coli* and a scanty growth of *Staph. aureus* were obtained, two secondary haemorrhages subsequently occurred, necessitating femoral, and later external iliac, ligation. On Feb. 11 *Bact. coli* only was cultured from the wound. The limb survived, and in due course secondary suture was successfully performed. The wound associated with the fracture of the right femur was heavily infected, and secondary suture was never possible. Severe toxæmia persisted and progressed, and it became necessary to make even freer posterolateral openings. On March 12 a large sequestrum involving three-quarters of the circumference of the femoral shaft was removed. Following this, high pyrexia of up to and above 103° F. (39.4° C.) persisted, while the discharge continued in undiminished quantities. Ten days after the operation a profuse secondary haemorrhage occurred from the right thigh. The femoral artery was ligated and the leg amputated through the site of the fracture, the flaps being left open. He died several hours later in spite of early and continued blood transfusion. During the period of observation he received two courses of parenteral penicillin, each of over 2 mega units, and sulphathiazole to the limits of tolerance.

From the wound associated with the fracture of the right femur *Str. pyogenes* and *Ps. pyocyanea* were isolated on admission. The streptococcus disappeared soon after penicillin therapy was instituted; *Ps. pyocyanea*, however, persisted, and was recovered from the wound on two further occasions before the operation of sequestrectomy, and again at the time of operation. At amputation the medullary cavity of the proximal fragment was filled with thick, greenish, tenacious pus, and similar greenish necrotic material had stripped the periosteum proximally. Heavy chemotherapy and wide exposure together failed to control the spread of Gram-negative infection. Since no other organisms were found it is probable that the microbe responsible for the progressive toxæmia, secondary haemorrhage, and death was *Ps. pyocyanea*.

Case II

Admitted on Nov. 7, 1944 a week after sustaining a compound fracture of the lower third of the femur together with a lesion of the sciatic nerve. A vaselined gauze plug was removed from the wound and the fracture site widely exposed. Pus had been denied escape by the plug. Secondary suture was performed on Nov. 20 after which pyrexia developed and persisted, and the sutured wound broke down to allow the escape of salmon pink pus. The fracture site was bathed in pus, pockets formed proximally necessitating further incisions, and toxæmia progressed in spite of free drainage and sulphathiazole therapy. On Jan. 20, 1945, amputation had to be performed in order to save the patient's life.

On admission an organism of the *Proteus* group and *S. aph. aureus* were isolated from cultures of the wound. No anaerobes were demonstrated. Within ten days of admission the staphylococcus had disappeared under the influence of penicillin treatment, and was never again present in any of the eleven bacteriological examinations which were subsequently performed, while *Proteus* or *Ps. pyocyanea* or both, were present on every occasion. At the time of secondary amputation *Proteus* group alone was cultured. Three days before amputation *Ps. pyocyanea* and a penicillin sensitive non-haemolytic streptococcus were isolated, and at the time of amputation *Proteus* group was again the only organism demonstrated. The non-haemolytic streptococcus was an evanescent hospital contaminant of no consequence while the patient was under penicillin therapy.

Case III

Admitted on Feb. 10, 1945, five days after wounding with a compound fracture of the lower third of the femur and a swinging temperature of up to 103° F (39.4° C). Systemic penicillin and sulphathiazole therapy were begun, and operation was performed on Feb. 12. More free exposure of the fracture site, and counter-drainage, were provided. The exposed muscles were covered with sloughs, and a foul-smelling discharge was present. He received a total of 1,920,000 units of penicillin and 40 g. of sulphathiazole. By the end of the sulphathiazole course the pyrexia appeared to be settling and the general condition to be improving, but on the sixth day after operation a severe popliteal haemorrhage occurred. Following control of the haemorrhage, it was only after plasma and 3 pints (17 l.) of blood had been given that the patient rallied sufficiently to permit of amputation with open flaps being performed. Further progress was uneventful.

A mixed growth of *Bact. coli* and *Ps. pyocyanea* was obtained from the foul smelling discharge at the time of the initial operation. No anaerobic bacteria were detected. At amputation *Ps. pyocyanea* was isolated from the wound, and the same organism was present in the three subsequent bacteriological examinations that were made. At he first and third of these it was associated with *Bact. coli* but at the second it was the only organism found.

Case IV

Admitted on March 14, 1945, 117 days after sustaining a comminuted compound fracture of the middle third of the femur associated with an incomplete lesion of the sciatic nerve. His general condition was very poor, there was high pyrexia up to 102° F (38.9° C), and the pulse rate varied between 90 and 100. The fracture was ununited, and was open in the depths of the wound. He had completed a course of parenteral penicillin (840,000 units) six days before admission. Parenteral penicillin therapy was started the day after admission, 2.24 mega units being given. Next day one of the wounds was enlarged, the medullary cavities of the proximal and distal fragments were opened, and free drainage was established. The general condition became critical on the table in spite of plasma transfusion. Ten days after completing the first course of penicillin a second course was started because infection was uncontrolled and the general condition was deteriorating. 1.28 mega units were administered. Four days later a meteoric descent in the general condition occurred, and on the morning of April 12 he was in such a state of circulatory collapse that the blood pressure was unrecordable and the radial pulse impalpable. An emergency circular amputation 1 in (2.5 cm.) above the site of fracture was performed in bed. After causing the gravest anxiety he recovered from this operation, but three secondary haemorrhages subsequently occurred, the first of which was almost fatal.

Proteus, together with a penicillin-sensitive strain of *Staph. albus* was present in two bacteriological examinations performed in the four days preceding our first course of penicillin. The staphylococcus never reappeared. At the time of the first operation *Proteus*, *Ps. pyocyanea*, and diphtheroids were isolated from samples of pus and excised bone. During the period between this operation and amputation ten bacteriological examinations were carried out. *Proteus* was present on every occasion—in eight alone and in two associated with diphtheroids. *Proteus* was isolated from pus and bone taken at the time of amputation, and was found in pus taken from the

stump on two subsequent occasions—once with *Ps. pyocyanea* and the second time alone. Anaerobic cultures performed on the swabs taken at the time of amputation were negative.

Case V

Admitted on Aug. 14, 1944, 133 days after receiving compound comminuted fractures of the upper thirds of both femora. There were high pyrexia up to 103° F (39.4° C), a rapid pulse rate, and a moderate degree of macrocytic anaemia. Both fractures were ununited, and were exposed in the depths of the wounds. The general condition was not improved by a parenteral course of 840,000 units of penicillin, and a second course associated with bilateral sequestrectomy was equally ineffective. *Ps. pyocyanea*, *Proteus* and *Bact. coli* were isolated from the wounds on both sides on Oct. 14, when a third course of parenteral penicillin was started. A radical excision of diseased bone was performed on both sides and the wounds were sutured over penicillin tubes. 3,670,000 units of penicillin were given parenterally and 324,000 units locally. Both wounds broke down and the general condition underwent progressive deterioration. *Ps. pyocyanea*, *Proteus*, and *Bact. coli* were isolated from the wounds on Oct. 18, and *Proteus* group and *Bact. coli* on Oct. 21. A penicillin sensitive coagulase positive staphylococcus appeared on Oct. 24 as a hospital infection, but persisted for less than four days as the patient was on penicillin at the time.

A fourth course of parenteral penicillin—1,600,000 units—was begun on Dec. 11, and sequestrectomy with total suture of the wounds was performed on the left side. *Proteus* was isolated from the wound. The wound broke down completely and the general condition deteriorated still further, necessitating a circular amputation through the site of fracture on Dec. 30. After amputation the patient's general health improved markedly and a successful secondary suture of the stump was performed on Jan. 4, 1945, when *Proteus* group was again cultured. The operation was performed under the protection of a fifth course of penicillin, 2,880,000 units being given.

The wound on the right side continued to discharge the fracture remained open, and union failed to occur. *Proteus* and diphtheroids were isolated on Jan. 26, and *Proteus* alone on Feb. 23 and March 5. On April 5 sequestrectomy was performed. *Proteus* was isolated from both pus and sequestrum taken for examination at the time of operation. Subsequently the fracture remained ununited and a sinus down to bone persisted until the patient was evacuated on June 5.

Case VI

Admitted on Jan. 5, 1945, 45 days after receiving a comminuted compound supracondylar fracture of the right femur involving the knee joint. The general condition was moderate, and there were a high swinging pyrexia up to 103° F (39.4° C), a rapid pulse rate, and a moderate degree of macrocytic anaemia. The fracture was ununited, and was exposed in the depths of the wound. On Jan. 9 a course of parenteral penicillin was begun, 3.84 mega units being administered. Radical excision of diseased bone was performed via A. K. Henry's incision on Jan. 18. This incision and the anterior wound were sutured, while the posterior wound was left open for drainage. While he was still on penicillin treatment suppurative arthritis of the knee developed and the general condition deteriorated alarmingly, necessitating a circular amputation through the site of fracture on Jan. 27. The flaps were left open. A dramatic improvement in the general condition followed this operation, and a secondary suture was successfully performed seventeen days later under the protection of a second course of parenteral penicillin (1.7 mega units).

Before starting penicillin therapy, *Proteus*, diphtheroids, and a non-haemolytic streptococcus were isolated from the wounds, while *Proteus* and diphtheroids were cultured from bone removed at the first operation. *Ps. pyocyanea* was isolated two days before amputation and again at amputation.

In all the above cases Gram negative organisms were isolated on many occasions, and pyogenic cocci, when present, occurred as evanescent hospital infections, and were rapidly controlled in every case by penicillin therapy. In two of the three late cases, Gram negative organisms were isolated from bone removed at operation as well as from the wound discharges. That pyogenic cocci were probably not present in bone in the remaining four cases is strongly suggested by the fact that one of us, in the examination of portions of bone removed at operation in 34 cases of late-infected compound fractures, found that all organisms isolated from the bone had already been identified in the wound discharges of 32. In the remaining two *Staph. aureus* was isolated from the bone though it had not been found up to that time in the wound discharge. In both cases it did, however, subsequently appear in the pus. Anaerobic examinations were performed in two of the recent cases and in one of the late cases. In all three the examination was negative. A series of 70 late-infected compound fractures studied by us at the rear-

base level indicated that non-haemolytic streptococci and diphtheroids did not affect wound-healing under penicillin treatment. The former were present in two of the above cases and the latter in three, each on isolated occasions. In the same series of 70 cases wound suture over a late-infected fracture with the aid of penicillin was successful in 14 out of 15 cases (93%) from which *Proteus*, *Ps. pyocyanea*, and *Bact. coli* were absent at the time of operation (*Staph. aureus* or *Str. haemolyticus* was present in 12 of these). On the other hand, suture was successful in only 28 out of 62 cases (45.2%) in which the above Gram-negative organisms were present. The only failure in the first group was almost certainly due to secondary infection with *Proteus*, which was found in the broken-down wound at the first dressing on the sixth post-operative day. The evidence for incriminating the Gram-negative organisms is therefore extremely strong in spite of the fact that virulence tests were not performed. Moreover, all of the six cases received adequate penicillin therapy, and in not a single instance did any benefit ensue. The three early cases in addition received sulphathiazole treatment, again without benefit. We may thus assume that infection with Gram-negative organisms resulted in illness severe enough to necessitate amputation in all of these six cases and to cause death in one of them.

It is more generally recognized that Gram-negative bacteria can display marked pathogenic properties on becoming established in the peritoneum, the urogenital tract, the meninges, the pleura, and the synovial membranes. The haemothorax infected with *Bact. coli* produces constitutional symptoms only slightly less severe than those produced by the Gram-positive infections. When drainage of an empyema has been established, it is the Gram-negative organisms that frequently are responsible for the persistence of chronic sepsis. *Ps. pyocyanea* and *Proteus* were found to be the infecting organisms in just as many pyopneumothoraces as was *Staph. aureus*. After seeing a number of haemothoraces in which Gram-negative infection had developed following prophylactic instillation of penicillin, it was felt that such instillation did more harm than good. The majority of uncomplicated haemothoraces progress satisfactorily with sufficiently frequent aspiration, and therefore it is unjustifiable to run the risk of introducing penicillin-insensitive organisms along with penicillin solution which may have been prepared under other than ideal conditions. Similarly, the prevalence of these organisms makes the prophylactic use of penicillin in the uninfected joint an unduly hazardous procedure, especially since aspiration alone gives satisfactory results in the uninfected haemarthrosis. The surgeon in the East must be fully alive to the possibility that *Bact. coli*, *Ps. pyocyanea*, or *Proteus* is frequently the responsible organism in a suppurative arthritis. If aspiration and penicillin therapy are used in such cases instead of free opening and drainage, disaster will indubitably follow.

Penicillin-insensitive *Staph. aureus*

Added to the hazards of Gram-negative infection is that due strains of *Staph. aureus* which are, or have become, resistant to intramuscular injections of penicillin in doses of 20,000 units three hours.

At the rear-base level it was found that the incidence of resistant strains of *Staph. aureus* was increased for some months after penicillin therapy was instituted in the forward areas in Burma. The overall incidence of strains insensitive to 0.04 unit of penicillin per ml. at the time of admission to the rear base was 17%, the sensitivity being determined by doubling dilution. In a group of 43 cases with late-infected compound fractures admitted to the rear base before penicillin therapy had been instituted no resistant pyogenic staphylococci were isolated, whereas in a similar group to whom penicillin had been administered in the forward areas 9.4% of *Staph. pyogenes* isolated on admission were resistant to 0.04 unit per ml. A point of interest was that of the *Staph. pyogenes* occurring in wounds as hospital infections 30% were resistant to 0.04 unit of penicillin per ml.

Major Ives, R.A.M.C., working in S.E.A.C., noted that among the pyogenic staphylococci isolated by him from wounds between January and June, 1945, the ratio of resistant strains was greater where the cocci were associated with a Gram-negative organism. The accompanying table, compiled by Major Ives, illustrates this point.

One effect of parenteral penicillin therapy in the forward areas is to reduce the rate of pyogenic coccal infection, unhealed wounds on admission to the rear-base hospitals. The degree of reduction is proportional to the adequacy of treatment. Conversely, the incidence of "Gram-negative" wound

Micro-organism	Total Examined for Sensitivity	Number Resistant	Percentage
<i>Staph. aureus</i>	134	53	39.6
<i>Staph. aureus</i> in association with <i>Bact. coli</i>	38	20	52.6
<i>Staph. aureus</i> in association with <i>Ps. pyocyanea</i>	16	8	50.0
<i>Str. viridans</i>	23	5	21.7
<i>Str. pyogenes</i>	50	0	Nil

is proportionately increased. In those wounds in which pyogenic cocci persist in spite of penicillin treatment the incidence of resistant strains is increased. It is thus debatable whether the association of resistant strains of *Staph. aureus* with Gram-negative organisms is due to the presence of the latter or to the previous inadequate penicillin treatment.

Penicillin-insensitive strains of *Staph. aureus* were found at the forward-base level in wounds affecting any part of the body, but it was in the compound femoral fracture that they proved most troublesome. With improved forward surgery, early in 1945, a further attempt was made to carry out delayed primary suture with drainage under cover of a penicillin "umbrella," the drug being given systemically. Many of the wounds appeared clean, and suture was performed on or about the fourth day after wounding. Some cases gave most gratifying results, but many others developed complications ranging from wound break-down to spreading sepsis and secondary haemorrhage, and in many cases this was due to the presence of a penicillin-resistant *Staph. aureus*. It was soon realized that it was unwise to carry out closure of a compound femoral fracture without first excluding the presence of a penicillin-insensitive staphylococcus. In the East delayed primary suture without bacteriological control is a dangerous procedure in the case of compound fractures of the femur; it is much safer to perform secondary suture on the tenth or twelfth day after a knowledge of the infecting microbes has been acquired.

Sensitivity and resistance to penicillin are purely relative terms. Different strains of staphylococci exhibit diverse shades of penicillin sensitivity. Pressure of work prevented routine testing of the degree of resistance at the forward base, but this was carried out at the rear base, where the method of serial doubling dilutions was employed. The range varied from twice as sensitive as the test organism (N.C.T.C. No. 6571A) to between 6,000 and 12,000 times more resistant than the latter, and between these extremes there is every gradation. Moreover, remarkable variations of sensitivity may occur in a very short space of time under the influence of inadequate penicillin therapy. In one case the resistance of an infecting staphylococcus was between 16 and 32 times as great as that of the Oxford staphylococcus; 6 days later it had increased to between 780 and 1,560 times as great as the test organism. During this period the patient was receiving 20,000 units of penicillin every three hours. Several other similar examples were met with and they indicate the importance both of giving an adequate dosage of penicillin and of performing serial sensitivity tests in this type of case.

It has been our clinical experience that where surgery is adequate a dosage of 20,000 units of penicillin every three hours, given by the intramuscular route, will control a staphylococcus whose sensitivity is equal to that of the Oxford staphylococcus, but that it will not control a more resistant organism. The more insensitive strains can be controlled provided that the dosage is stepped up sufficiently.

One patient with a united compound fracture of the upper end of the humerus and a sinus leading down to bone was infected with a *Staph. aureus* twice as resistant as the Oxford staphylococcus. Penicillin therapy was started. In view of the resistance of the staphylococcus 30,000 units were given every three hours instead of the usual dosage of 20,000 units. 48 hours later the sinus was excised, radical removal of bone performed, and the wound totally sutured under no tension and without drainage. After operation pyrexia persisted and a superficial sinus appeared in the wound from

hich a *Staph aureus* was recovered. The wounds showed signs of inflammation. The dosage was increased to 40,000 units every three hours. The temperature immediately fell to normal, the signs of inflammation rapidly disappeared and within four days the sinus ad closed.

A second case of great interest in this respect was that of a patient who had an infected compound fracture of the neck of the femur. His general condition was very poor, and was deteriorating rapidly in spite of the fact that he had been on penicillin treatment for 28 days. He was receiving 20,000 units every three hours. At this stage one of us was asked to see the case. There was a high swinging pyrexia of up to 102° F (38.9° C), the pulse rate was rapid and the general condition was the cause of grave concern. Infection was due to a *Staph aureus* 16 times more resistant than the Oxford staphylococcus. The dosage was increased to 200,000 units every two hours—i.e., almost sixteenfold—and maintained at this level for 19 days. There was an immediate response on the temperature and pulse charts, and a striking improvement in the general condition. Within four days he was fit enough to have the end of the femur removed in safety. The bone was grossly diseased and there was a suppurative arthritis of the hip. His subsequent progress was satisfactory. Massive penicillin therapy probably saved his patient's life. He received the enormous total dose of 23.2 mega units.

It is clear that the dosage of penicillin necessary to control infection due to *Staph aureus* is dependent upon the sensitivity of the organism and whenever it can be done the sensitivity should be tested before starting treatment. It should be possible to compile tables equating dosage to sensitivity. In treating infections due to resistant strains of *Staph aureus* continuous administration of penicillin would achieve a more exact equation between resistance and dosage, and great economy in expenditure of the drug. This would be the ideal technique of treatment were a satisfactory method of continuous administration available. Staphylococci up to, say 16 times more resistant than the Oxford staphylococcus are within reach of effective penicillin therapy provided the dosage is stepped up to meet the occasion.

Inferences

The Gram negative bacilli are a common cause of prolonged low grade infection in bone following compound fractures in the East, and are capable of producing severe spreading infection serious enough to lead to death or amputation.

Penicillin insensitive strains of *Staph aureus* are frequent. The less resistant strains can be controlled effectively by stepping up the dose of penicillin to a suitable degree.

Further work devoted to the control of penicillin insensitive organisms is urgently required.

We wish to thank Lieut-Gen G Wilson, DMS India Command, for permission to publish this paper, and to acknowledge the help given by Brig F Harris D D H A P, India, Brig Grant Massie Consulting Surgeon, India Command, Brig J Bruce Consulting Surgeon, Fourteenth Army, and Brig M F Nicholls Consulting Surgeon Allied Land Forces South East Asia under whose direction this work was carried out.

MUNICIPAL HOSPITAL MEALS

As a result of a special inquiry the Manchester Public Health Committee has made a number of recommendations on hospital meals. One of them is that a catering supervisor be appointed to each of the city's municipal hospitals. It is also suggested that, when conditions permit all patients should have their meals served on individual trays and also that a full rotation of diet should be resumed, with a choice of two dishes. "It is not enough," says the report, "that patients on leaving hospital should be in such a condition that the clinical symptoms of illness have been cleared up or that a surgical operation has been successfully performed and the site healed sufficiently to permit of removal to home. The diet and treatment should be such that the strength of the patients is built up sufficiently to restore the wasteage caused by illness and to send them away from the hospital as fit as possible." Commenting on the Public Health Committee's recommendations, the *Manchester Guardian* says in an editorial, "It will always be easy to find excuses for continued neglect of the patient's nutritional needs unless some permanent body or official is specifically charged with the duty of seeing that this document's admirable recommendations are put into effect." According to the *Hospitals Year book*, dietitians are at present employed at only two of Manchester's voluntary hospitals and none at all are to be found at the municipal hospitals. London has dietitians at only fifteen of its hospitals.

MALNUTRITION IN RECOVERED PRISONERS OF WAR AND INTERNEES

REPORT OF 10 CASES EVACUATED FROM THAILAND

BY

L. M. GUPTA, M.B., B.Sc.

Capt. I.M.S. / I.A.M.C., Medical Specialist

This work on malnutrition in R.A.P.W.I., British other ranks, was undertaken at the request of Lieut-Col G A Ransome, I.M.S., Local Adviser in Medicine to XII Army, who, during his tour of P.O.W. camps in Thailand after the Japanese capitulation, considered it advisable to send an experienced team of medical officers and nursing sisters to deal with the serious cases in Prachuab Kirikan. The military situation at the time, however, did not permit the entry of nursing sisters into the area, and only two medical officers were sent.

With the conditions in the camp and the lack of facilities for treatment and nursing, it was decided to risk immediate evacuation by air, to give these men a better chance of survival. This was accomplished successfully, and no undue distress was noticed in the patients. The maximum height attained by the aeroplane never exceeded 10,000 feet (3,050 m). It will be seen from the report that all these patients were anaemic, the lowest with a haemoglobin of 5 g %. Only ten of these cases are described below.

These patients were taken prisoner at Singapore in February, 1942. The majority of them kept in good health for that year, but repeated attacks of malaria and hard physical labour while on a poor rice diet caused an increasing sick rate. Deficiency diseases appeared by the middle of 1943, with the general health progressively deteriorating but with periodic augmentation of the diet by additions of meat and eggs and Red Cross supplies (received twice only) some improvement followed, though relapses occurred soon after. Bowel disorders, once started, made conditions worse, and supervening chronic diarrhoea produced a picture of severe malnutrition.

After the capitulation these patients received a complete course of antimalarial treatment and intensive vitamin therapy (oral and parenteral) for about one week before being evacuated into this hospital at Rangoon. The clinical descriptions as given in this report are of cases seen from the time of admission into this hospital. Some of these patients had already started improving. While in this hospital every patient received 12 tablets of multivitamin daily and suppressive mepacrine in addition to the specific treatment enumerated with each case.

All pathological data are recorded in tabular form with a synopsis of the patients' clinical state and past history for easy reference. The diet while in P.O.W. camps was variable, but chiefly consisted of rice. The average daily diet, light diet, and high-protein diet which they received in this hospital are given at the end of the paper.

Case I

Cpl A, aged 34. *Past History*—Maintained fairly good health in 1942. In 1943-4 suffered from repeated attacks of malaria and one attack of clinical dysentery, with progressive deterioration of health and marked weakness but without much loss of weight. In April, 1945, he had scrub typhus, after which he developed swelling of both feet and legs and a marked degree of anaemia. He had 1,000 ml of blood transfused before coming to this hospital.

Clinical Features—Still severely anaemic, Hb, 5 g %, red cells, 1,650,000 per cmm, marked oedema of the lower extremities and slight ascites. Tongue pale and flabby, but no redness. No visual complaints, but suffered from slight deafness. Heart slightly dilated, apex in the nipple line, with a diffuse cardiac impulse, no clinical enlargement of the right side. Haemic murmur present. BP 118/76. Lungs clear. Abdomen slightly distended, liver and spleen not palpable, tenderness over the lower abdomen, with a thickened caecum. Reflexes all present and equal. No sensory changes. Skin generalized pedicular infection, texture normal.

Treatment—Injection of thiamine chloride 50 mg. for 1 day, followed by 20 mg. daily for 5 days. Reconstituted double-strength human plasma 250 ml. This was repeated one day later, and 500 ml of citrated whole blood was transfused next day. Light diet was given for three days, which was well tolerated, this was followed by minced high protein diet and iron by mouth.

Progress.—The oedema disappeared after plasma transfusion, and in two weeks the patient showed marked clinical improvement; anaemia improved and blood protein reached almost normal level.

Case II

Pte. B., aged 26. *Past History.*—No illness in 1942; had repeated attacks of fever in 1943, once diagnosed as M.T. malaria. In 1944 had several attacks of fever and beriberi, with oedema of legs, which improved with rest and the diet supplemented by milk and eggs. In 1945, six weeks before capitulation, started diarrhoea, which had been persistent. Later developed oedema of lower extremities and genitals, with ascites.

Clinical Features.—Patient grossly emaciated; pinched facies and prominent ribs; hands and legs swollen. Tongue magenta red and depapillated. Heart normal. Lungs clear. Abdomen: Scaphoid and tense; marked loss of areolar tissue; free fluid present; liver and spleen not palpable; tenderness over the entire colon; caecum thickened, also tender. Bowels: Loose watery stools, over 20 a day. Reflexes could not be elicited because of extreme wasting of the muscles. Skin dry and scaly.

Treatment.—Injection of thiamine chloride 50 mg. for 3 days, 20 mg. for 10 days, and 10 mg. for 6 days. Nicotinic acid 300 mg. daily for 10 days, followed by 6 injections of nikethamide 1 ampoule daily. Routine course of sulphaguanidine for 7 days, followed by sulphathiazole 4 days, checked the diarrhoea; but later *E. histolytica* cysts were found in the stools and specific treatment was started. Reconstituted double-strength human plasma 1,500 ml. was given in six injections of 250 ml. daily. Diet: In the early stages this consisted of drinks of whey, vegamite soup, and curds; pulped liver was then added, and the diet gradually increased to a minced high-protein diet including 8 oz. of fresh liver daily. The patient tolerated this diet after two weeks' stay in hospital.

Progress.—The oedema subsided slowly and steadily. Appetite was regained, and with the diarrhoea controlled he has made steady progress. (Still in hospital.)

Case III

Gnr. C., aged 37. *Past History.*—Had repeated attacks of malaria 1942-4; dysentery and beriberi in 1945, one month before capitulation.

Clinical Features.—Extremely emaciated, with sunken features, prominent ribs, and "matchstick" legs. Slightly dehydrated. Anaemia marked; Hb, 7 g. %. Complained of slight deafness and dimness of vision. Had been using glasses: vision 6/9; with glasses 6/6 previously, but now 6/9 not improved with glasses. Disks healthy. Tongue: Atrophic glossitis with multiple shallow furrows and marginal redness. Heart: Diffuse apical impulse; boundaries and sounds normal. Complained of slight cough, but lungs clear; x-ray report, "lung fields normal." Abdomen: No distension; liver just palpable; spleen not felt; no tenderness of colon. Bowels loose, watery; 6 to 7 stools per day. Reflexes normal. Oedema of lower limbs present. Skin rather dry, with pediculus infection and scabies.

Treatment.—Injection of thiamine chloride 50 mg. for 3 days and 10 mg. for 10 days. Six injections of nikethamide 1 ampoule daily. Routine course of sulphaguanidine, and 500 ml. of reconstituted double-strength plasma. Diet: Light diet till diarrhoea subsided, then minced high-protein diet. Iron was given when diarrhoea had stopped, and injections of liver when the anaemia proved to be aplastic.

Progress.—Improved gradually; oedema diminished quickly after plasma transfusion and disappeared after another week.

Case IV

Pte. D., aged 28. *Past History.*—Dysentery, repeated attacks of malaria, and beriberi in 1942. Beriberi every year since; also several attacks of malaria. Admitted to hospital in April, 1945, when oedema of extremities and genitals, with ascites, supervened.

Clinical Features.—Moderately well nourished, with marked pallor; red cells, 2,600,000 per c.mm.; rather dyspnoeic; neck veins empty at 60. Tongue magenta red, with loss of superficial epithelium. Heart dilated; apex 1/4 in. (0.6 cm.) outside the nipple line; no obvious enlargement of the right side; systolic murmur present over mitral and pulmonary areas. Lungs: Signs of basal congestion present. B.P. 110/80. Abdomen: Slightly distended; liver enlarged 2 cm. and spleen 4 cm. below the costal margin; caecum and sigmoid colon not palpable. No diarrhoea on admission. Reflexes present but sluggish. Skin normal. Patient had a fever with rigor, and a blood specimen showed B.T. trophozoites.

Treatment.—Complete antimalarial course. Injection of thiamine chloride 50 mg. for 3 days and 20 mg. for 14 days; nikethamide, 6 injections of one ampoule daily. While on a high-protein diet relapsed into a diarrhoea, which settled with nikethamide injections and light diet. Later tolerated high-protein diet.

Progress.—Improvement slow but steady. No dyspnoea, subsided and tongue became more normal. Heart remained slightly dilated; oedema of legs disappeared gradually in a week.

Case V

Gnr. E., aged 37. *Past History.*—Had synovitis in the right knee in 1942, which has been recurrent. In 1943 had malaria thrice and dysentery four times; in 1944 malaria nine times; and in 1945 scrub typhus and several attacks of malaria.

Clinical Features.—Extremely emaciated, with moderate anaemia. Red cells, 3,500,000 per c.mm. Tongue sore, with marginal redness. Heart and lungs normal. Abdomen: Slightly distended; liver and spleen not palpable; caecum and sigmoid colon tender with thickening. Bowels: Loose watery stool 8 to 10 times a day. Flexes all present but sluggish. No sensory change. Skin rough dry, with scabies. No oedema. Right knee-joint swollen and tender, with marked spasm of the quadriceps. Two oz. (57 ml.) of viscous yellow fluid was withdrawn on aspiration. Examination of the fluid showed no organisms, no acid-fast bacilli, few cells (polymorphs and lymphocytes, the latter predominating). Culture sterile. X-rays: Right knee—an area of rarefaction seen below the intercondylar eminence just medial to the midline; chest—apart from generalized increase in the lung markings no abnormality seen.

Treatment.—Injection of thiamine chloride 10 mg. daily for 10 days; nikethamide, 6 injections of 1 ampoule daily. Diet: Light diet till diarrhoea controlled, then minced high-protein diet and iron.

Progress.—Slow improvement; diarrhoea stopped, tongue became normal. Very little gain in weight. The knee showed little change.

Case VI

Sgt. F., aged 25. *Past History.*—No illness in 1942. Several attacks of malaria and occasional diarrhoea in 1943-4. No dysentery or beriberi in July, 1945.

Clinical Features.—Extremely emaciated and slightly dehydrated. Anaemia marked; Hb, 6.5 g. %, with an icteric tinge of the skin and sclera. Tongue: Mild atrophic glossitis; no soreness. Heart: Mild tachycardia; size normal; haemic murmur present. Lungs: Occasional moist sounds. X-ray chest: "Lung fields clear." Abdomen: Scaphoid, with marked loss of fat; liver and spleen not palpable; caecum and sigmoid normal. Reflexes brisk. No sensory change. Skin lax, rough, and dry, with scabies and a few septic spots.

Treatment.—Minced high-protein diet. Citrated whole-blood transfusion 500 ml. and iron from the fourth day of admission.

Progress.—Diet tolerated well. Rapid improvement followed blood transfusion.

Case VII

Sgt. G., aged 25. *Past History.*—Several attacks of malaria in 1942. In May, 1943, first attack of dry beriberi, and repeated attacks of malaria. In 1944 an attack of dysentery and also malaria. In April, 1945, had dysentery again, followed by chronic diarrhoea and pain in the legs (pellagra).

Clinical Features.—Markedly emaciated and anaemic; Hb, 8.6 g. %. Dimness of vision correctable with glasses (had used glasses before). Tongue normal. Heart normal. Lungs clear. Abdomen: Slightly distended; liver edge just palpable, not tender; spleen not palpable; caecum and colon normal. Reflexes: Knee-jerks could not be elicited owing to extreme atrophy of muscles; ankle-jerks present but sluggish. No sensory change. No oedema. Skin normal.

Treatment.—Tolerated light diet very well, and after four days was on high-protein diet and iron.

Progress.—Steady improvement; uneventful.

Case VIII

Pte. H., aged 29. *Past History.*—Had dysentery and dengue in 1942, beriberi in 1943, with several attacks of malaria and an attack of typhus fever. In 1944 had several attacks of malaria. In 1945 had malaria thrice and was unconscious every time. In July developed oedema of lower extremities and ascites.

Clinical Features.—Fairly well nourished; slightly anaemic. Hb, 11 g. %; red cells, 2,700,000 per c.mm.; colour index, 1.45; M.C.V., 118 c.μ. Tongue normal. Heart normal. Lungs clear. Abdomen: Distended; free fluid present; liver not palpable; spleen enlarged 2 cm. below costal margin. No diarrhoea. Swelling of feet at legs. Reflexes normal. Skin: Texture normal.

Treatment.—Minced high-protein diet tolerated well from the beginning. I.V. quinine 6 gr. (0.4 g.) daily for 6 days. I.M. injection of liver extract 32 ml. first week, 16 ml. second week. Iron was given from the fourth day.

Progress.—Although on suppressive mepacrine after a complete course of antimalarial treatment, the patient was running a slight

(a) — Observations on admission, (b) — Observations two weeks later, before evacuation Stool: — no ova or cysts; no pathogenic organisms,

fever on alternate days. Blood films showed no parasites, but the temperature responded to quinine therapy. The megalocytic anaemia improved with liver. Very good response to treatment.

Case IX

Fus. I., aged 30. *Past History*.—No illness in 1942. In 1943 had ulcers on both legs and beriberi. In 1944 had malaria 16 times; in 1945 malaria 20 times and dysentery once followed by beriberi.

Clinical Features.—Moderately emaciated; slightly anaemic. Hb, 10 g. %. Tongue red, depapillated, and sore. Heart and lungs normal. Abdomen: No distension; liver and spleen not palpable; tenderness over the lower abdomen. Bowels normal. Reflexes normal. No oedema. Skin normal.

Treatment.—Minced high-protein diet and iron from the fourth day.

Progress.—Satisfactory improvement.

Case X

Sgt. J., aged 45. *Past History*.—No illness in 1942-3. Had malaria twice in 1944, and an attack of cerebral malaria in 1945, when he developed a bed-sore.

Clinical Features.—Moderately well nourished; wasting of the left pectoral muscles. Moderate anaemia. Hb, 8.3 g. %; red cells, 3,700,000 per c.mm. C.I., 0.8; M.C.V., 64.7 c.μ. Tongue: Marginal redness, and depapillated. Heart normal; slight tachycardia. Lungs: Scattered crepitations; had haemoptysis once while in this hospital. Sputum: Acid-fast bacilli present. X-ray chest: "Tuberculous infiltration left apex." Abdomen: No distension; liver not palpable; spleen just felt. No diarrhoea, no oedema. Reflexes normal. Large bed-sore, granulating. Skin normal.

Treatment.—Absolute rest; high-protein diet with extra fat (total calories, 4,500); linct. codein. at night; morphine 1/4 gr. (16 mg.) subsequent to haemoptysis; iron mixture.

Progress.—With rest the temperature came down to normal, which was subsequently maintained. Appetite was good, and he appeared to have gained weight. Anaemia improved.

Light Diet as Given in Hospital

(Approximately—170 g. Protein; 3,000 Calories)

8.00 a.m.	Porridge made with milk	8 oz. (227 g.)
	Scrambled or lightly boiled eggs	2
	Bread	2 oz. (57 g.)
	Butter	1 oz. (28 g.)
	Tea with milk and sugar	10 oz. (284 g.)
10.00 a.m.	Curds or Horlick's	10 oz.
11.00 a.m.	Tomato juice with milk	10 oz.
12.30 p.m.	Minced chicken or raw pulped liver	6 oz. (170 g.)
	Creamed potato	3 oz. (85 g.)
	Carrots or peas	2 oz. (57 g.)
	Egg custard with jam	6 oz. (170 g.)
3.30 p.m.	Egg flip	10 oz. (284 g.)
6.00 p.m.	Chicken soup	6 oz. (170 g.)
	Minced liver	6 oz.
	Creamed potato	4 oz. (114 g.)
	Egg custard	4 oz.
	Fruit jelly	4 oz.
8.00 p.m.	Ovaltine with milk	10 oz. (284 g.)
10.00 p.m.	Horlick's	10 oz.

High-protein Diet as Given in Hospital

(Approximately—215 g. Protein; 4,000 Calories)

8.00 a.m.	Porridge made with milk	8 oz. (227 g.)
	Eggs, poached or scrambled	2
	Bread	4 oz. (114 g.)
	Butter	1 oz. (28 g.)
	Tea with milk and sugar	10 oz. (284 g.)
10.00 a.m.	Curds or Horlick's	10 oz.
12.30 p.m.	Boiled chicken or fish	8 oz. (227 g.)
	Creamed potato	4 oz. (114 g.)
	Carrots or peas	3 oz. (85 g.)
	Milk pudding	6 oz. (170 g.)
	Bread	2 oz. (57 g.)
	Butter	1 oz. (28 g.)
	Tea with milk and sugar	6 oz. (170 g.)
2.30 p.m.	Egg flip	8 oz. (227 g.)
4.00 p.m.	Bread	2 oz. (57 g.)
	Butter	1 oz. (28 g.)
	Jam	1 oz. (28 g.)
	Tea with milk and sugar	10 oz. (284 g.)
6.00 p.m.	Chicken soup	8 oz. (227 g.)
	Fried liver	6 oz. (170 g.)
	Potatoes	4 oz. (114 g.)
	Green vegetables	6 oz. (170 g.)
	Egg custard	6 oz.
	Fruit jelly	4 oz. (114 g.)
	Bread	2 oz. (57 g.)
	Butter	1 oz. (28 g.)
7.00 p.m.	Tea with milk and sugar	6 oz. (170 g.)
10.00 p.m.	Horlick's or ovaltine	10 oz. (284 g.)

Average Daily Diet in P.O.W. Camps

Breakfast: Pap rice with 1/2 tea-spoonful sugar and tea		
Tiffin: Rice, vegetable stew, and tea		
Dinner: Rice, meat stew, rissole, and tea		
(Risssole—Rice and meat or vegetables mixed and fried into a cake)		
Rice	14 oz. (400 g.)
Vegetables	6 oz. (170 g.)
Meat	3 oz. (85 g.)
Cooking oil	1 oz. (28 g.)
Sugar	1 oz. (28 g.)

In the early days of 1942 the diet in P.O.W. camps was supplemented by rations which our troops were allowed to carry with them. When these were exhausted they lived on polished rice. In the beginning the allowance for fish or meat was 4-6 oz. (114-170 g.) this being gradually reduced to 1-3 oz. (28-85 g.) and, the supply being irregular, often 7 to 8 days passed without meat or fish. In places where supplies were steadier the average health was fair. The issue of rice varied from 12 to 17 oz. (340 to 480 g.) per head per day in different camps, but individuals rarely consumed their total allotment, thereby losing the energy value. Milk was scarce, and the allowance of sugar of 1 oz. a day diminished towards the end and was finally cut out entirely. Animal protein, even when rations were available (3 oz. of meat per head per day), was inadequate. More often than not a plate of meat stew hardly contained a piece of meat. Vegetables issued were of a poor quality—e.g., pumpkin, radish, sweet potato, and marrow. Green leafy vegetables, if any, were negligible in amount. The vitamin content of the diet was very low, and with the increasing needs during repeated attacks of fever and wastage associated with bowel disorders, deficiency diseases appeared. About the end of 1942 there was an outbreak of avitaminosis—sore scrotum, sore tongue, angular stomatitis, etc.—which terminated after treatment with rice polishings, palm oil, and peanuts. Through local purchase and with the small sum of money they received, some were able to supplement their diets in small quantity with peanuts and bananas when available, and thus avoid the maladies of chronic starvation. The treatment of the sick was poor and inadequate, and convalescence, when allowed, was too short; the result being that, once ill, a man hardly had a chance of complete recovery. Thus repeated attacks of malaria and dysentery caused a large number of deaths.

Summary

Although a large number among the R.A.P.W.I. showed evidence of minor degrees of malnutrition, only ten cases from the severe group are reported.

The clinical pictures as presented are not those characteristic of a single vitamin deficiency, but are those that would follow a vitamin complex deficiency (multivitamin deficiency). Large doses of vitamin were therefore administered. Aneurin was given to aid metabolism—assuming that the reserves would be low though specific signs were absent.

In P.O.W. camps the diet was extremely low in proteins. Consequently, hypoproteinaemia and wasting resulted, the oedema of legs being the result of low blood proteins. The plasma proteins of all these patients were low—average 5.5 to 6.5 g. %, the lowest being 4.3 g. %. The presence of oedema was not proportional to the total plasma proteins (Case III, with plasma proteins of 5.2 g. %, had no oedema, while Case I had marked oedema even with plasma protein of 5.9 g. %); but, from previous extensive experience of such cases, one can say that a correlation would have been revealed by estimations of the A.:G. ratio, which unfortunately could not be done here owing to lack of proper facilities.

Response to high-protein diet, and plasma transfusion in severe cases (I, II, and III), has been satisfactory.

Anaemia was present in all cases, both megalocytic (III and VII) and microcytic (V and X). Response to haematonic therapy was good in both groups.

Weights have not been recorded owing to the lack of a reliable weighing machine, but a gain in weight was noticed in all cases except Case V.

Most of the patients gave a history of beriberi, which appears to have been diagnosed on the presence of oedema of legs only. It has been included in the past history on the patient's own statement.

While an adequate follow-up of the cases was impracticable, the progress of all patients between admission and evacuation two weeks later was satisfactory. Therapy designed to correct the deficit protein, vitamin, and haemoglobin contents of the body produced the anticipated improvements. The multiple deficiencies in each case necessitated multiple medication, and for this reason accurate appointment of the credit to any one therapeutic agent is not possible.

I should like to end with an expression of gratitude to all those who made this investigation possible. The valued contribution of Capt. J. C. Valentine, I.A.M.C., on haematology and biochemistry and the co-operation of the nursing staff, have been very much appreciated. I should also like to thank Lieut.-Col. G. A. Ransom, I.A.M.C., for his continued help and encouragement. My special thanks are due to Major-Gen. W. E. Tyndall, C.B.E., M.S., Director of Medical Services, Headquarters, Allied Land Force South-East Asia, for permission to publish this article.

R.A.P.W.I.: AN IMPRESSION

BY

R KEMBALL PRICE, M.D., M.R.C.P.

Lieut-Col R.A.M.C., Officer in Charge of a Medical Division

These recovered Allied prisoners of war and internees were a group of people who had been in Japanese hands for the last 3½ years. The majority were captured at Singapore in February 1942. The cases were British other ranks and civilian men, women, and children. The total number was about 1,000. Much of the material on which these notes are based has been the subject of clinical research—particularly by neurologists, ophthalmologists and biochemists. Some interesting information has been obtained and will be published in detail elsewhere. The purpose of this article is to put on record the general impression of a group of such patients admitted to a British general hospital in Southern India.

Conditions

These varied from forced labour on the notorious Burma-Siam Railway, which is said to have cost a life for every sleeper laid, to comparative comfort in some civilian internment camps. The appreciation and gratitude of the patients varied inversely with the conditions from which they had been rescued. The British other ranks were all happy and contented. Their standard of discipline, judged by turn out, saluting etc., was higher than the majority of garrison troops. Most of the civilians were good patients, too, but a few were extremely difficult. One man went so far as to suggest he was better treated by the Japanese. This was countered by the suggestion that he must have been a collaborator, and no more was heard from him on the subject. It must be remembered that most of them had been leading a life of luxury right up to the time of internment, whereas many of the soldiers had been through hell even before they were captured. The main hardships in the camps were lack of food, bad living conditions and sanitation and the harsh and often brutal treatment by the Japanese guards. Rations varied in different camps and also with the work being done, those on heavy work getting more than those on light duties. Anyone admitted to hospital was immediately put on half rations. This undoubtedly increased the mortality in diseases such as pulmonary tuberculosis. It may be said in passing that the Japanese appear to have treated their own sick with equal callousness.

Rice was the main food. In 1942 18–20 oz (510–570 g) a day was the average. The ration was cut in 1943 to 12 oz (340 g), thus a man going sick got only 6 oz (170 g). For a long time soup made from potato tops was the only regular addition. Later small quantities of meat, fish, and sugar were added, and later still they began growing their own vegetables. The common feature of all diets was gross deficiency in fat, protein, and vitamins, all patients showed great loss of weight, and most had signs of hypovitaminosis. One patient, aged 31 who had no serious illnesses managed to keep a record of his weight—Before capture, 12 st 10 lb (79.8 kg), August, 1942, 10 st 4 lb (65.3 kg), February, 1944, 10 st (63.5 kg), December, 1944, 9 st 7 lb (60.4 kg), May, 1945, 8 st 6 lb (53.6 kg), June, 1945, 7 st 10 lb (49 kg), July, 1945, 6 st 7 lb (41.3 kg). Overcrowding occurred in all camps and sanitary arrangements were bad. Medical supplies were practically nonexistent, but British medical officers were generally available.

Discipline was rigid, and failure to bow to the guards, even if unintentional, met with severe retribution. Punishment for the most trivial offences was brutal. One British NCO had his jaw smashed with a rifle butt for stealing a turnip, and another was severely beaten up for protesting against his party being taken on a double work shift. Cases of maltreatment without any excuse at all seem to have been rare. The Japanese attitude to most of the women internees was one of indifference. To the children they were kind. The latter were easily the fittest of our patients. While this was due partly to sacrifices by their parents, there were cases where Japanese guards gave presents of sweets and other luxuries to them. On one occasion when Japanese generals visited a camp they distributed chocolate to the children. The fact that this had been obtained from looted Red Cross parcels was only known later.

The first to arrive at this hospital was a batch of 200 British other ranks who had come on an aircraft carrier. They were all walking cases, and anyone who saw them could never forget the experience. All showed emaciation, and some had oedema of the legs, but their morale can only be described as terrific. There was great superficial gaiety, but beneath this was a deep rooted fear which showed itself when their faces were at rest. The frequent blinking and the shaking hand were a legacy of what they had been through. Their condition was aptly compared to that of the whipped dog returning to his master. The policy adopted by this hospital was to give them as much liberty as possible, and they were allowed to come and go as they pleased. While this made things difficult for the medical officer who never found all his patients in the ward at any time it was very good for the patients' morale. Special rations were provided, and with the aid of Red Cross parcels a generous and varied diet was supplied. All who were considered fit to travel were passed on as rapidly as possible. "Fit to travel" was the only criterion. Much good work was done by the ladies of the British Red Cross, who were always around helping to entertain the patients and ease their readjustment. An impromptu dance held on the day after they arrived was well supported and a great success. Cinema shows in the wards were given twice a week.

Medical Aspects

All patients showed malnutrition. As most had been released 10 to 14 days before admission to this hospital they had already gained weight—some as much as a stone (6.4 kg). In addition the Japanese had increased their rations and released a number of Red Cross parcels during their last weeks of imprisonment.

Nutritional oedema due to hypoproteinaemia was very common. Most of these cases came to us labelled 'beriberi'. In some cases the oedema had been accompanied by hepatic enlargement and ascites. A number of these had telero-diagrams taken of their hearts, which were found to be normal in size and shape. Not a single case of proved cardiac beriberi was seen. Macrocytic anaemia was present in many cases with colour indices as high as 1.5. With improvement in the general condition the blood showed an increase in red cells and haemoglobin, and also a return towards the normal picture.

Jungle sores were common. In some cases they were infected with the Klebs-Loeffler bacillus, which had given rise to local or generalized peripheral neuritis. A history of pellagra was often obtained, but here again objective evidence was slight. Scurvy was not seen.

Neurological Conditions

The most striking cases were those showing degeneration of the nervous system. They fell into three groups, of which the following were the main characteristics: (A) amblyopia, ataxia, and nerve deafness, (B) spastic paraplegia, (C) peripheral neuritis. Examples of Group A syndrome had been reported in prisoners released earlier from Rangoon gaol, so further cases were expected. Different parts of the nervous system appeared to show varying degrees of vulnerability, and the optic nerve, posterior columns, and auditory nerve tended to suffer in that order.

The amblyopia cases all complained of some degree of visual deterioration. It had started usually 6 to 9 months after capture, and had gradually increased. In others the onset had been sudden. Some degree of improvement was the rule, but complete recovery rare. Men who had not worn glasses previous to capture were now unable to read, others could read headlines only. Many complained that they could see things better at the side than in front. On examination they were found to have reduction of visual acuity, a central scotoma, and pallor of the temporal halves of the optic disks. This temporal pallor, which was striking, was also seen in a number of men who did not complain.

The ataxia, which was most pronounced in the legs but was seen also in the arms in some cases, was associated with loss of sense of position, vibration, and deep pain. The area of loss to vibration usually ended sharply at a level corresponding to some spinal segment.

By comparison with amblyopia and ataxia, nerve deafness was rare but a few cases of the complete syndrome were seen.

In one of these cases the ataxia was thought to be partly vestibular in origin. It would indeed be surprising if the vestibular branch of the eighth nerve escaped entirely when the auditory branch was involved in the degenerative process. This syndrome was regarded by neurologists as a deficiency disease. There was some difference of opinion as to its nature. Lack of vitamin A was considered at one time, but the consensus of opinion was that it was due to shortage of the B complex.

The cases of spastic paraplegia formed a small but sharply defined group. They all came from two camps, and had developed about the same time within a period of six months. They showed gross spasticity, walking on the tips of their toes and unable to put their heels to the ground. Deep reflexes were exaggerated and plantar responses extensor. Cases occurred in men who had suffered less privation than average. One N.C.O. had been in charge of a cookhouse and fed comparatively well. It seemed probable that the cause here was some toxic factor, and neurological opinion favoured the diagnosis of lathyrism.

The cases of peripheral neuritis were not infrequently associated with signs of Group A syndrome, giving a mixed picture. Others, as already stated, were due to diphtheritic infection. A number were left, however, in which a diagnosis of neuritic beriberi seemed justifiable.

Diseases Present

Pulmonary tuberculosis was the most serious disease occurring commonly among them. This had already taken a considerable toll of lives before release. More than 50 cases were received here, showing all stages of the disease. The high incidence is not surprising considering the lowering of resistance by malnutrition, overwork, and intercurrent infection, particularly malaria. The overcrowded living conditions predisposed to the spread of the disease. Most of the cases are now doing well on sanatorium treatment, and it would seem reasonable to assume that the majority of these patients would never have developed the disease had they been leading normal lives. Thus it may be argued that as a group they have a higher basic resistance than a comparable group who have developed the disease in civil life.

The military patients had nearly all had repeated attacks of malaria. Some reported as many as 50 attacks. Though accurate counting becomes difficult after five or six relapses, it is certain that the majority of them had had many attacks. In sharp contrast were the civilians, most of whom had been living in Malaya for years before the war. Many of them had not had a single attack, and few had had more than one or two. This suggests an acquired resistance to the local strains. All Service cases were given a full course of mepacrine, if they had not already had it, and were instructed to take a suppressive dose for a further six weeks. It was felt that this would make freedom from relapse fairly certain during the journey home.

A remarkable feature of our series was the low incidence of dysentery. Our dysentery ward never had more than a dozen cases in it at any time. A considerable number of patients gave a history of proved amoebic dysentery. This had cleared up completely without any specific treatment, and full examination, including sigmoidoscopy, showed no abnormality. This confirmed an impression already gained—that in this disease the soil may be more important than the seed.

A few cases of sprue were seen, all in civilians, and they were our only patients who had suffered from being released. The sudden change-over to a full diet was too much for them and had a disastrous effect. One arrived in *extremis* and died within 24 hours of admission. Two others gave us a great deal of anxiety before they turned the corner. With strict dieting and transfusion they eventually made a good recovery.

Conclusion

To summarize, it may be said that the condition of these patients was, on the whole, better than might have been expected. The greater resilience of youth was seen in the more rapid recovery in Service cases. This was particularly marked in those showing nutritional oedema.

The medical attention these men and women had received from British doctors in the camps calls for the highest praise.

Working usually without x rays or other equipment, they made accurate diagnoses, which were confirmed when full investigation was possible. Where screening could be done pneumothoraces had been induced and maintained. The full and careful notes which the patients brought with them of inestimable value to us in carrying on with their treatment. Finally, it may be said that our patients presented an example of survival of the fittest.

My thanks are due to Col. W. J. Officer, O.B.E., commanding 114 British General Hospital, for his help and criticism.

TREATMENT OF ACUTE OTITIS MEDIA BY DECONGESTION

BY

W. OGILVY REID, M.B., Ch.B., B.Sc., F.R.C.S.

Spendiary Aural Surgeon, the Children's Hospital, Birmingham

The role of ephedrine as a decongestive agent in the nose is well recognized. Its value in the treatment of middle-ear inflammation does not seem to be known.

Some three years ago I first used it to decongest the mucosa "pouting" through perforations in the acutely inflamed tympanic membrane in acute otitis media. The anticipated result was obtained. The mucosa became less turgid, the opening through the membrane was correspondingly enlarged, and drainage was facilitated. Resolution was thereby accelerated. The effect was the same, of course, whether the opening followed myringotomy or rupture of the drum. It may well be that some of the ephedrine solution also found its way into the middle ear itself and exerted its helpful decongestive action on the mucosa lining the cavity and the tympanic end of the Eustachian tube, with consequent improved drainage through the latter. Having enlarged the opening through the drum as described, the process of drainage was further enhanced by the instillation of glycerin drops after the ephedrine. These, of course, are helpful by virtue of their osmotic action. To this combination of ephedrine followed by glycerin the term "decongestion-osmosis" is applied.

The experiment was later tried of instilling the ephedrine solution into the ear in early cases of acute otitis media with an intact, congested, but not yet distended tympanic membrane. The effect was surprising. After a few applications, at four hourly intervals, the drum became decongested, inflammatory appearances were dispelled, the landmarks became more clearly apparent again, and all evidences of a process towards resolution were demonstrated. Pain disappeared and the patient felt better. In the majority of cases the condition cleared up, being apparently aborted by the treatment. The term "decongestion" is applied to this procedure.

The rationale of the latter cannot readily be fully explained. It is empirical. My assumption is that the reduction in hyperaemia which takes place (obviously) on the outer surface of the drum results in a reflex mucosal decongestion inside the tympanic cavity and adjacent Eustachian tube, with consequent re-establishment of drainage through the latter. The irreversible process of an inflamed middle ear with exudate shut off beyond a blocked Eustachian tube is thus not allowed to develop, and so resolution by the usual sequence of events which takes place in favourable cases of inflammation can proceed unhampered.

Details of Treatment

The solutions used are 2% aqueous solution of ephedrine alkaloid or of ephedrine sulphate for the decongestion and pure glycerin when osmosis is also required.

(a) *Decongestion-osmosis*.—This is indicated in established cases of acute otitis media when there is a perforation or a myringotomy opening which is inadequate owing to inflammatory congestion. Clean discharge from the meatus. Then, with the patient lying on his side with the affected ear uppermost, instil a few drops of the ephedrine solution into the meatus. After ten minutes' interval instil a few drops of glycerin. The sequence should be repeated at least thrice daily until a freely flowing mucopurulent discharge is obtained. This should be achieved within the maximum of a few days. The usual lines of treatment may then be followed, I myself being partial

to the use of guttae argyrol 5% at this stage—either simply instilled or, when all signs of acute inflammation have gone, by the displacement method (Reid, 1939).

(b) *Decongestion*.—This is indicated in early cases of acute otitis media (i.e., within the first 48 hours usually) with an intact but inflamed non-bulging drum. The ephedrine solution only is instilled into the affected ear, in the same way as above described—a few drops being left to act for about five minutes. Repeat at least three daily. The case should be reviewed in three days, the patient being told to report earlier if the pain has not gone after the first three treatments.

Both the above procedures can be simply carried out by the patients with the assistance of someone at home, but they must, of course, report within the times specified—or earlier if pain persists.

Results

These are excellent. The logical decongestion-osmosis always proves beneficial when indicated. As regards the decongestion, it can be claimed that the majority of cases of acute otitis media abort with this treatment if it is instituted early enough. Also, no risk would appear to be involved. In no case has mastoiditis developed in consequence of delay in applying other lines of treatment because of decongestion having been employed. With this method of treatment myringotomy is much less often necessary, rapid resolution with an intact tympanic membrane being the rule.

The following figures of myringotomies done in the out-patient department theatre at the Children's Hospital, Birmingham, in 1944 and 1945 show the striking drop in the number of those operations since I introduced decongestion therapy in April, 1945.

	1945	1944
January	98	184
February	94	116
March	110	230
Decongestion therapy introduced		
April	63	147
May	36	137
June	17	155
July	14	78
August	14	73
September	8	43
October	17	92
November	12	89
December	20	66

The figures for January and February of 1946 are 16 and 8 respectively, compared with 98 and 94 for the corresponding months in 1945, when decongestion was not used.

Finally, it should be mentioned that this line of treatment is not advocated in conjunction with chemotherapy, in view of the masking effects of the latter on the middle-ear appearances, the changes in which should be carefully observed. Anyway, the use of chemotherapy should be reserved for only the more virulent forms of acute otitis media.

A CASE OF INDIGENOUS MALARIA IN NORTHERN IRELAND

BY

N. V. BIRRELL, M.B., M.R.C.P., D.P.H.

Formerly Surg. Lieut.-Cmdr., R.N.V.R.

The "ague" has been present in England throughout historic times, but in recent generations it was little heard of until 1917. From September that year onwards until 1919 almost 600 locally contracted cases of malaria occurred in England. The cause of that outbreak was the return of large numbers of infected military personnel from malarious areas abroad, chiefly Greece, Mesopotamia, and Africa, to areas in England where anopheline mosquitoes were prevalent. Cases were scattered over South-East England, especially in coastal areas, and a small epidemic occurred in the Isle of Sheppey, in Kent. This outbreak was described in a report to the Local Government Board (1919).

Cases of endemic malaria were rare between the wars, but Shute (1944) drew attention to the possibility of an increase

of indigenous malaria after the war then in progress was ended and when large numbers of infected Service personnel would be returning from abroad. One such case is here described, and it is considered to be of especial interest as it occurred in Northern Ireland—an area in which malaria does not appear to have been previously recorded.

Case History

The patient was a member of the W.R.N.S., aged 24, who was admitted to a naval auxiliary hospital in Londonderry on July 16, 1945. She gave a history of headache and attacks of shivering and sweating for a week previous to admission. Her temperature, which was 101° F. (38.3° C.) on admission, was normal next day. It rose to 105° F. (40.6° C.) on July 18. The tongue was heavily furled, but no physical signs were found to account for her pyrexia. She was well again on the 19th, but on the 20th her temperature rose to 104° F. (40° C.). The temperature chart was by now typical of tertian malaria, and a blood slide taken that day showed a heavy infection with benign tertian parasites. She responded well to treatment and there were no complications. The spleen was not palpable at any time. Blood counts showed 4,500,000 red cells per cmm. and a haemoglobin of 90%. The patient had never had any similar illness before, and she had never been outside England and Northern Ireland.

Comment

The chief point of interest in this case lies in trying to trace the place where infection occurred. For the transmission of malaria the necessary factors are: (1) the existence of human carriers of malaria with gametocytes in the peripheral blood; (2) the existence of suitable mosquito vectors; (3) certain further conditions which are not yet fully understood, but which include a suitable temperature for the development of the parasite in the mosquito. Studies of malaria in England and in other temperate climates have shown that, under the conditions there, cases of malaria tend to occur in two main seasonal groups. Primary infections may develop symptoms either in the late summer and early autumn—that is, when conditions for transmission are most suitable—or in the spring months of March, April, May, or even June. It is presumed that this second group of cases have been infected during the previous summer but that the infection has remained latent for a period of from 6 to 9 months. This phenomenon has been discussed by Shute (1939).

The subject of this present case had spent 1944 at Southampton and Newhaven, with occasional brief visits to her home at Braintree, in Essex—an area where malaria is known to occur. In March, 1945, she was drafted to Londonderry and remained there until she took ill, except for a visit to Braintree from April 20 till May 1, on leave. That visit may be left out of consideration as a possible time of infection as the early summer mosquitoes would not yet be hatched out. It remains to decide whether this patient was a latent case, infected in England during the previous summer, or was, in fact, infected in Northern Ireland.

Her work kept her in the naval dockyard by day, while her living quarters were in a Nissen hut, one of eight in the grounds of a large house about a mile north of the centre of the town. Search of the area around these quarters showed that anopheline mosquitoes were breeding in a small pond about 200 yards away. Larvae from this pond were kindly identified for me by the Ministry of Health Malaria Laboratory, Horton Hospital, Epsom, as *A. maculipennis*. This is the most usual British malaria-carrying mosquito, and it was no doubt breeding in other suitable places in the district. Carriers of malaria were numerous in the Londonderry area during the spring and summer of 1945, as during the previous autumn the local Territorial regiment, numbering several hundred strong, had returned home after five years in the Middle East and Italy. Of these men some had been demobilized, while others were home on leave from time to time. Moreover, primary and relapse cases of malaria were almost always under treatment in the hospital from among the many hundreds of naval and Air Force personnel stationed in the area, of whom a large proportion had served in malarious areas abroad during the war.

It must now be considered whether it is likely that the processes of infection of a local anopheline, development of the parasite within it, infection of the patient, and incubation of the disease could have taken place before July 9, which was the date on which the first symptom appeared. The time taken for the parasite to develop in the mosquito is largely governed

by temperature. At an average temperature of 70–80° F. (21.1–26.6° C.) the cycle for B.T. parasites is completed in about 10 days. At 60° F. (15.5° C.) it takes 30 days. It has been stated to take about 14 days at 62–68° F. (16.6–20° C.). The spring of 1945 was an unusually mild one, and so too was the month of June. Records supplied by the meteorological officer of a nearby naval air station showed that from June 3 to 7 the maximum daily temperatures were from 61 to 65.6° F. (16.1 to 18.6° C.), and that from June 17 onwards the daily maximum was never below 60° F. (15.5° C.). There was a spell of warm weather from June 18 to 24, when for a large part of the day the temperature was 65° F. (18.3° C.) or higher and twice exceeded 70° F. (21.1° C.). These temperatures, however, do not necessarily represent those at which the adult female mosquitoes were living during this period, as they spend much of their time indoors, in buildings where they can get meals of blood, especially in animal-houses. In the absence of such accommodation it may be assumed that they would find the Nissen huts, warmed by stoves and containing sleeping Wrens, acceptable alternatives, and with temperatures generally higher than out of doors.

Mosquitoes which came out with the first wave of summer hatchings, usually in the first week of June, could be given a week in which to become infected, and, allowing 12 days for the incubation period in the patient, would still have 17 or 18 days in which to develop the parasite within them. At the temperatures of June, 1945, that does not seem an unreasonable period to allow. The first week of July was also warm, with maximum temperatures of over 70° F. (21.1° C.) on two days.

I believe that such evidence as is available supports the contention that this case of malaria was infected in Northern Ireland. It would be well for practitioners there, as elsewhere in the British Isles, to be on the look out for similar indigenous cases this spring and summer.

I am indebted to the Medical Director-General of the Navy, for permission to publish this case.

Medical Memoranda

Coma as Onset in a Case of Malaria in England

Although many medical men in this country are becoming increasingly familiar with the signs and symptoms of malaria, it is possible that some may not recognize as being due to that complaint a case of coma in a patient not previously suspected of malaria. The following case history is that of a patient in whom two brief periods of fever and, later, some degree of anaemia were the only pointers to the possibility of malarial infection—until the evening on which a sudden coma resulted in blockage of the cerebral vessels with the merozoites and corpuscular fragments, and a very high fever developed.

CASE HISTORY

A previously healthy young male subject, aged 23, had spent eleven months in West Africa and had returned to England six weeks before his admission to Redhill County Hospital. During his stay in West Africa he had taken 10 gr. (0.65 g.) of quinine daily as prophylaxis, but discontinued this on leaving Africa. A few days after his return to England he had two very brief bouts of fever. He felt apathetic and rather sleepy often during the succeeding weeks, and for a week before his admission to hospital he had been resting at home on iron therapy from his own doctor for anaemia. Twenty-four hours before admission he complained of some pain in his right arm, but the coma and the high fever (105° F.: 40.6° C.) which occurred on the following evening were unexpectedly sudden in their development.

At admission he was lying still, deeply comatose, very pale, and showing a temperature of 104.2° F. (40.1° C.). Breathing was rapid (36), deep, and very noisy. Pupils were moderately dilated and did not react to light. There was no neck rigidity. Tendon jerks were all grossly exaggerated and there was bilateral ankle clonus. Plantars were both definitely extensor and abdominal reflexes were all absent. The spleen tip was felt 3 in. (7.6 cm.) below the left costal margin. The lungs showed only a little bronchitis.

A blood film was taken, and 20 gr. (1.3 g.) of quinine bihydrochloride was given intravenously. Increased hyperventilation followed

the injection, but with subsequent tepid sponging the temperature fell and the patient rapidly recovered consciousness. The blood film showed large numbers of malignant tertian parasites.

Next morning the patient was quite alert and bright, but was very pale and the conjunctivae showed a trace of bile. The spleen was still 3 in. below the costal margin. The blood count was: Hb. 40%; R.B.C., 1,720,000; C.I., 1.17; W.B.C., 3,260 (P. 52%, L. 40%, M. 8%). Tendon jerks were still increased, but much less than the previous night; there were only a few catches of ankle clonus on each side, and the plantars were now flexor.

The succeeding days on quinine bihydrochloride 10 gr. (0.65 g. t.i.d. and mepacrine 0.1 g. t.i.d. were marked by steady improvement. The size of the spleen gradually diminished, the tendon jerks slowly became normal, and the colour improved. On the third day the quinine dose was reduced to 5 gr. (0.32 g.) t.i.d., and ferri ammon. cit. was given, at first 45 gr. (3 g.) daily, but soon the dose was raised to 90 gr. (6 g.) daily. Six days after admission the spleen could no longer be felt, but there was still a tendency to exaggeration of tendon jerks in the legs. The abdominal responses were now normal.

The patient was discharged on the seventeenth day, after a further five days on 0.02 g. of pamaquin (thrice daily); and by then his blood count was: Hb. 70%; R.B.C., 3,860,000; C.I., 0.92; W.B.C., 6,450 (P. 72%, L. 20%, M. 7%, E. 1%). The temperature remained normal after the second day, and after the first examination no parasites were found in the blood. When seen two months after the attack the patient showed no anaemia and reported no further relapses.

COMMENT

A case of malignant tertian malaria is described which had been suppressed by prophylactic quinine, but which, about eight weeks after the end of prophylaxis, suddenly revealed itself by the symptoms of profound coma with quadriplegic tendencies, hyperpyrexia, and overbreathing. The diagnosis, which was immediately suspected because of the development of these symptoms in a patient lately arrived from West Africa, appeared most probable when it was found that he was also profoundly anaemic, and showed marked splenomegaly and some signs of bronchitis. Strong antimalarial treatment was immediately beneficial, and subsequently his progress has been uninterrupted.

G. H. JENNINGS, M.D., M.R.C.P.

Redhill County Hospital, Edgware.

Delayed Healing of a Vesico-vaginal Fistula by Inflammatory Reaction

This case is worthy of record because of the notorious chronicity of vesico-vaginal fistulae, and also because of the very extensive surgical procedures required when vaginal closure is not possible.

A native girl aged 19, a para-1, was seen by me early in May, 1945. She gave a history of a long difficult labour about nine months previously, and of continual incontinence of urine dating from about the time of her puerperium. Vaginal examination revealed a large vesico-vaginal fistula, easily admitting the tip of my middle finger, in the anterior fornix. Although palpation led me to suspect considerable scarring, I decided to attempt operation. I then found, however, that the cicatrization made it impossible to pull down the cervix and see the fistula. I attempted to suture, working "blind," but abandoned this as technically impossible. Two sutures which I managed to insert cut through the friable tissue when tied. I then scraped the edges of the fistula with a small sharp scalpel in the faint hope of causing enough tissue reaction to close it or to reduce it in size.

For some weeks after this operation there was no sign of improvement, and I began to consider intravesical closure, and, if that failed, colpocleisis as recommended by Cameron (1925) in such cases. It was, however, suggested to me by a colleague that ureteric transplantation might offer a better chance of cure, and it was decided that this should be attempted in two months' time. The girl meantime went home to her village.

She returned at the end of August, saying she was now better. To my surprise vaginal examination revealed that the fistula had indeed closed and there was nothing to be felt in the anterior fornix but a mass of scar tissue. While the fistula had undoubtedly closed, I gave a very guarded prognosis with regard to its remaining so, especially in the event of another pregnancy.

This case is interesting because of the considerable size of the fistula, and because all sign of reaction to operative intervention locally had disappeared long before she was sent back to her village. It suggests that in cases of inaccessible vesico-vaginal fistulae it might be well to try to promote a local reaction and then wait some considerable time before undertaking more drastic procedures.

Reviews

PHYSICAL CHEMISTRY OF CELLS AND TISSUES

Physical Chemistry of Cells and Tissues By Rudolf Höber. With the collaboration of D. I. Hitchcock, J. B. Bateman, D. R. Goddard and Wallace O. Fenn (Pp 676 42s) London J and A Churchill 1945

Many readers will welcome this book. Physical chemistry is not represented in the biological or medical field by a separate subject, nor would such a specialization be desirable. Cells and tissues are heterogeneous systems composed of aqueous and lipid phase, of fibres, and these structures are the material of all who study the properties of living matter, whatever their own method or approach.

This book is subdivided into a number of sections written by five different authors. The first section, by D. I. Hitchcock, is an outline of the biologically important basic principles of physical chemistry. The mathematical treatment of the subject would have been made clearer by examples and by being less condensed. The reader is often referred to other textbooks when a more extended treatment is needed. J. B. Bateman's contribution is entitled 'Large Molecules', it deals with the electrical and chemical forces determining the properties of these molecules and with the way in which they interact. This section also contains a discussion of the use of x ray methods for the study of fibres and of the properties of monolayers and similar membranes.

These two physical sections are followed by the discussion of biological systems, R. Höber has written admirably on the properties of the protoplasm and its surface, on the response of cells to environmental factors, in which he includes a discussion of great value on the action of narcotics on cellular activity, and on the transport of substances across cell membranes (passive transfer, absorption, secretion). D. R. Goddard deals with cell respiration and respiratory enzymes, this account is extremely instructive. There is a section on contractility by W. O. Fenn which was unfortunately written in 1942, for since then a great deal has been discovered concerning the biochemical properties of muscle proteins especially myosin and this knowledge is to-day the central point of discussion on contractility.

The book contains a great number of references, and it is an especially pleasing feature that the valuable pioneering work of earlier generations is given full recognition. In the preface the editor gives a brief exposition of the point of view from which this book has been written, and he stresses the fact that it is chiefly the outlook of the physicist which has been adopted. In the study of living matter the dividing line between chemistry and physics becomes so blurred as to be of little significance, but it is true that the successes of the biochemist and the organic chemist, in the field of therapeutics and in applied biology in general, have tended to stress the importance of the organic chemist. There is little doubt that the book will help in correcting this tendency and that it will be of use to all—chemists, physicists, and biologists alike.

PROTOZOOLOGY

Protozoology By Richard R. Kudo, D.Sc. Third edition, revised and with two new chapters. (Pp 778, illustrated. \$9.00) Illinois: Charles C. Thomas

The popularity of Prof Kudo's textbook is evidenced by the fact that though first produced only seventeen years ago a third edition is now issued. The present volume is some 80 pages longer than the last edition, and is profusely illustrated with more than three hundred excellent black and white figures, and four new half-page colour plates of the human malaria parasites.

Part I some 190 pages, discusses very thoroughly in six chapters the appearance, habits, physiology, and reproduction of protozoa generally. Part II deals systematically in 44 chapters with the taxonomy and special biology of the very numerous genera and species of free living and parasitic protozoa. Each chapter ends with a list of references to literature concerning the organisms discussed. The final chapter is devoted to a discussion in 30 pages of the technique of collection, cultivation, and observation of protozoa. A 47 page index terminates the book.

The medical protozoologist deals with a very small number of protozoa, but concerning them he requires detailed information. On the other hand, the parasitic protozoa of man and domestic stock form for the systematic protozoologist only a small section of his subject and, therefore, only some 80 pages are devoted in this book to these parasitic forms. The human intestinal amoebae (10 pages) and the human malaria parasites (11 pages) are fairly fully described, but only four pages are allotted to the human trypanosomes, and *T. rhodesiensis* is dismissed in 12 lines. Most of the important trypanosomes of domestic stock are mentioned—some are omitted—but the description of the morphology of these species is insufficient for the purposes of identification. The book cannot, therefore, be recommended to the medical man or veterinary surgeon wishing detailed information about protozoa in his particular field. It will, however, be of value for reference to the medical or veterinary protozoologist, since it covers systematically the whole field, relates together the various orders, families, and species, and describes large numbers of organisms which may occur as contaminants in material sent for examination. The sections on the free living protozoa of water will be of value to those responsible for water supplies.

In spite of its increased length the work still retains its compact form and excellent print.

PRACTICAL OBSTETRICS

The Midwife's Textbook of the Principles and Practice of Midwifery By R. W. Johnstone, M.D., F.R.C.S. Ed., F.R.C.O.G. Second edition. (Pp 311, illustrated. 18s) London: Adam and Charles Black.

Prof Johnstone's excellent book is written for pupil midwives but its text is so clear, concise, and so well illustrated, and its teaching so logical and effective, that it can be recommended to a much wider circle of readers. Medical students and bus practitioners alike would find much of profit in these pages. The author has omitted discussion of general anatomy, physiology, and pathology, referring those who may wish for further details of these to the books already published for pupil nurses. In their place he has introduced more obstetrical details of interest and importance than one usually finds in a work of this size. The anatomy of the pelvis and the physiology of menstruation and pregnancy are dealt with in the first 48 pages of the new edition. The succeeding chapters deal with the foetus, the principles of antenatal care and hygiene, labour in the various presentations, the normal puerperium, asphyxia neonatorum, pathology of pregnancy, pathology of labour, pathology of the puerperium, drugs and solutions in common use in midwifery, obstetrical operations in domiciliary practice, antenatal and postnatal exercises, the newborn child and radiography in obstetrics. Two valuable concluding chapters are those on midwifery in relation to public health and the history of midwifery.

The section dealing with post partum haemorrhage is excellent, and particular mention should be made of the valuable advice on preventive treatment. The midwife is reminded that good midwifery in its widest sense, antenatal and intrapartum is necessary to reduce the incidence of post partum haemorrhage to a minimum.

ELECTRICAL INJURIES

Der elektrische Unfall als pathologisch-anatomisches, klinisches und rechtliches Problem. By Dr. Fritz Jenny. (Pp 144, illustrated. 12.50 Sw francs) Bern: Medizinische Verlag Hans Huber.

To readers who understand German there are one or two volumes available on the subject of electrical and lightning injuries. To these may now be added this little book written by Dr Jenny of Lucerne. The author deals in orthodox fashion first with the technical details which determine the severity and location of electrical injuries. This preliminary section is followed by a description of the effects as they appear in the various organs and tissues. Brief case reports are given and there are a number of excellent illustrations. The vexed problem of the cause of death after electrocution is considered in a special chapter. There is some reference to the subject of electroneurosis, and the studies of Cerletti and Bini upon electrically induced convulsions find a place. Dr Jenny does not

have much to say upon the historical aspects of his subject. A useful bibliography is given, but unfortunately it is far from complete. Medical problems connected with lightning-stroke are referred to only very briefly, as are the questions of accidents occurring from x-ray apparatus.

One may summarize by describing this book as a competent introductory thesis, interesting and well produced. In the case of such a specialized subject, however, a full-dress monograph is sadly needed. It is a matter for comment that no manual, large or small, exists in the English language upon electrical injuries. This is a defect which should be remedied, for electrical injuries and their sequelae already play a not inconsiderable part in industrial medicine, and the problem is one we might expect to increase rather than to diminish.

SPRAINS OF THE INSTEP AND OF THE KNEE

Entorses du Cou-de-pied et Entorses du Genou. By L. Léger and C. Olivier. (Pp. 218; 85 figures. 200 francs.) Paris: Masson et Cie.

This interesting monogram is really a study on Leriche's classical discovery that many of the results which follow on a sprain can be abolished by the early injection of novocain into the damaged area. The authors open with a discussion of what is meant by sprain, and give a most precise account of its ascertained anatomy, physiology, and pathology. They then discuss the mechanism by which sprains of the instep are produced, their results and treatment, with, of course, special reference to the work of Leriche.

A similar examination is made of sprains of the knee, including more severe injuries such as those which involve rupture of the crucial ligaments. The late results of such injuries and the most modern methods of repair are fully described, and illustrated by excellent diagrams. In conclusion, chronic arthritis and painful knees of obscure origin are discussed.

This is a monograph of considerable importance. The authors are evidently well acquainted with the whole literature of their subject, which is accurately summarized, and they possess a wide and varied practical experience. The line diagrams by which they illustrate the text are admirably designed and beautifully executed. It is a fine study and a valuable addition to an important branch of surgery.

Notes on Books

The Epic of the Red Cross; or, The Knight-Ernt of Charity, by FERNAND GIGON (Jarrolds Ltd.; 12s. 6d.), is the life story of a Genevan, Jean-Henri Dunant, who in 1864 became the recognized founder of the Red Cross International Society. He was contemporary and the counterpart of Florence Nightingale. Both were roused to action by the sight of thousands of untended wounded and dying soldiers—he at Solferino and Florence Nightingale at Scutari. Dunant had a grim fight in carrying out his propaganda work. No one from the Emperor Napoleon III downwards could withstand his persistence, till at last his plan for the methodical organization of a body of voluntary workers, in aid of wounded soldiers, came into being. His programme was to foster the establishment, during international peace, of charitable societies, whose aim would be to organize bands of well-trained workers. The German Emperor William I, as Grand Master of St. John of Jerusalem, took a deep interest, as did all other European crowned heads, in the Red Cross work of the Geneva Convention. Since the first world war began the work of the Joint Committee of the British Red Cross Society and the Order of St. John, in aid of suffering humanity, has assumed gigantic proportions, reaching a figure of £50,000,000. Fernand Gigon's book is confined to Dunant's epic struggles for the realization of his dream, which came true before he died in 1910 a worn-out but happy man.

A fifth edition has now been published by J. and A. Churchill (12s. 6d.) of *Practical Biochemistry for Students of Medicine*, by A. T. CAMERON and Dr. FRANK D. WHITE, of the Faculty of Medicine of the University of Manitoba. It appeared first in 1930, and the authors' guiding principle continues to be that this book should, if anything, err on the conservative side, employing old tested methods rather than newer, less tested ones. In the new edition they have revised the tests concerned with the clotting of blood, so as to illustrate the chief features of Quick's theory. Brief directions are included for estimating hippuric acid excretion as a measure of liver function, and for estimating urobilinogen in urine, and the account of a basal metabolism determination has been revised to conform more closely to present clinical apparatus.

Dr. BERYL TWYMAN has written a modest little book on *Some Minor Ailments of Childhood* with the subtitle *Being Hints to Mothers* (E. and S. Livingstone: 9d.). It is a happy mixture of common sense and sound teaching on physical and psychological disorders. The poetry quoted at the end serves as a reminder that mothers north of the Tweed have probably had a better general education than their southern sisters. It is a safe and suitable booklet to supply to intelligent mothers at child welfare clinics.

After only three years the South African textbook on *Medical Jurisprudence* by Drs. W. F. RHODES, I. GORDON, and R. T. has reached its second edition and is well on the way to becoming a classic. This edition contains a considerable amount of new material, and the earlier text has been largely rewritten. The chapters on identity, mental illness, workmen's compensation, the constitution and functions of the South African Medical Council, the registration and certification of births and deaths, and medical negligence are new. The book covers that field of forensic pathology which is common to most countries, but not fully enough to compete with the fuller textbooks from this country or the United States. Within the Union of South Africa, however, it is unique and will become increasingly popular and indeed indispensable. The publishers are the Stewart Printing Company of Capetown, and the price is 32s. 6d.

The changes which have been made in the second edition of *Nitrous Oxide-Oxygen Anaesthesia*, by F. W. CLEMENT (Henry Kimpton 22s. 6d.), are those of the detail rather than the scope of the original text. The author is evidently aware of the considerable apprehension on the part of anaesthetists concerning the dangers of anoxia, and of the growing criticism of nitrous oxide on that account. He does not hesitate, therefore, to include a somewhat apologetic chapter in which this question of anoxia is reviewed and the critics are answered. Even though some of the views expressed may not be acceptable to every anaesthetist should read this book, as an excellent exposition of nitrous oxide-oxygen anaesthesia as practised by the McKesson school.

Preparations and Appliances

FINGER TRAPS FOR BANJO SPLINT

Dr. G. R. P. ALDRED-BROWN, consulting physician, Royal National Hospital for Rheumatic Diseases, Bath, writes:

For many years past, and especially since the rubber shoe age, I have used plaited finger "traps," as they are known in the toy trade, for obtaining extension and correcting alignment of fingers. The banjo splint used is the ordinary type with stout wire circle fixed to a metal palm rest, and the wire attachment consists of either a leather gaiter or a plaited splint.

These finger traps obviate the use of adhesive tapes and rubber band pulleys. The tip of the finger fits into the trap and is gripped firmly. The elasticity is imparted by the plaited raffia, which exerts a continuous traction. The wire ring should be notched in five places to receive the fine string which is threaded through the top of each finger trap by means of a carpet needle. It is advisable to have the wire circle sufficiently large to allow for the length of the fingers plus the length of the finger traps.

The wire can be bent to any required shape, and in fact should be more of a loop than a circle if it is desired to correct ulnar deviation of the fingers.

The finger traps are obtainable, price 9d. each, from Messrs. P. Clive and Co. Ltd., Back 68, Cocker Street, Blackpool.

Messrs. Ward, Blenkinsop & Co. Ltd., of Liverpool, offer phenylmercuric nitrate in solution for sterilizing wounds, for treating vaginal infections caused by *Trichomonas vaginalis*, and for treating tinea and epidermophytosis. It is supplied as a 1% solution in diethyl glycol. They also offer dithranol, which is used for the same purposes as chrysarobin, but chiefly for psoriasis, for which it has been found effective. Dithranol, which is dihydroxyanthranol, is offered in the sixth Addendum to the B.P. 1932.

BRITISH MEDICAL JOURNAL

SATURDAY APRIL 27 1946

THE LORDS ON THE HEALTH SERVICE

Public debate and concern about the Government's hospital proposals continue. Medical and lay opinion has been perplexed by a division of opinion in the medical profession on the Minister's proposal that he should become the owner of all the hospitals in this country. This arose because of the Consultants' Services Committee's resolution that it approved the transfer of ownership of hospitals provided the composition of the Regional Boards is satisfactory. This resolution was submitted to the constituent bodies of this committee. Of these the Royal College of Surgeons, the Royal College of Obstetricians and Gynaecologists, and the British Medical Association have stated their opposition to the suggested transfer. When the matter was debated by the Comitia of the Royal College of Physicians last week the following resolution was passed. "That the College approves the central direction and co-ordination of the general policy of hospitals provided the composition of Regional Boards is satisfactory." The Consultants and specialists, in so far as they are represented by the three Royal Colleges, have, therefore, not approved of the resolution of the Consultants' Services Committee. The Council of the British Medical Association has expressed itself unequivocally in opposition. It is fair, therefore, to say that the majority of the profession through its representative institutions finds itself at variance with the Minister of Health on one of the principal features of the Bill shortly to be debated in the House of Commons.

Many of the grounds for misapprehension were expressed by several speakers in the informative debate opened last week in the House of Lords by the President of the Royal College of Physicians, Lord Moran. The timing of events made a full discussion impossible. As the Government spokesman in the debate observed, the proper occasion for the Government to submit their case was during the second reading debate on the Bill in the Commons, and subsequently when that stage was reached in the House of Lords. At the end of the debate Lord Listowel therefore asked Lord Moran to withdraw his resolution, "in view of the danger of precipitating a premature decision." The Lords, therefore, had to confine their remarks to statements in the White Paper and avoid reference to clauses in the Bill. Lord Moran probably timed his motion in the general anticipation that the second reading of the Bill would take place in the House of Commons before Easter. But this reading has been postponed until May. In spite of these limitations the Lords taking part found the opportunity to express opinion on the various aspects of the

hospital problem in a way which should be most helpful to those who have to carry on the debate in and out of Parliament.

Lord Moran moved to resolve "that this House, while regretting any measure which might impair the efficiency of the general practitioner service, welcomes proposals for the better co-ordination of the hospital services of the country." There could obviously be no dissentient voice to this unexceptionable proposition. Asking whether "a drastic reorganization" of the hospital system of the country was necessary, he concluded that the answer was to be found in the hospital surveys made by the Ministry of Health during the war. He pointed out that one-third of the 93,000 beds in the 1,059 voluntary hospitals in England and Wales were provided by hospitals having fewer than 100 beds. These hospitals, he believed, were too small to fulfil the functions of a first-class hospital, and in many of them major surgery was performed by men without surgical training, "and the duties of physicians are usurped by those who have not had the training of the physician." Of the 152,000 beds in municipal hospitals 78,000 were for general purposes—i.e., excluding infectious diseases, etc. Of the 78,000 beds 29,000 were in public assistance institutions—institutions which provided little but food and shelter. On top of this disturbing state of affairs were the difficult financial circumstances in which the voluntary hospitals were now placed. This meant that they would have to call upon the Government for a considerable sum of money for the hospitals, and with public expenditure on this scale some measure of public control would be necessary.

Lord Moran then asked the question, "Who is to exercise that control?" Was it to be the local authorities or the Minister working through the regions? He considered that "local authorities had behaved with great patriotism in accepting the proposals of the Minister in the White Paper, which must be very unpalatable to them." He went on to observe that professional discussion during the past few years had been dominated by the fear that hospitals would come under the control of local authorities. "It is because this White Paper," he continued, "appears to lift that menace from the profession that so many consultants and specialists are reconciled to the passing of the voluntary system." We should perhaps reiterate at this point the fact that the three Royal Colleges which represent the great majority of consultants and specialists in this country are not only not reconciled but are opposed to the passing of the voluntary system. After discussing briefly why the profession regarded local authority control as a menace Lord Moran stated that if hospitals are not to be controlled by local authorities they must be controlled by the Minister. "But when we proceed to ask the Minister who exercises this control—whether it implies the transfer of ownership of hospitals—an agreement ceases, and there is great difference of opinion in the profession on this particular point."

Pursuing the question of ownership, on which he made it plain he was speaking personally and not for his colleagues, Lord Moran said that if the change of ownership took place they would gain co-ordination of hospitals,

financial peace, progress unhampered by poverty, and freedom from the local authority "menace." "Further, the Minister of Health has refused to blunt the growing edge of medicine, for the teaching hospitals are left alone." Perhaps we should complete this observation by referring to the Minister's proposals to take over the ownership of the teaching hospitals and to appoint their governing boards and chairmen. To the question "What do we lose?" Lord Moran gives his own answer: "We lose the voluntary system." And to his next question: "Why has the name of the voluntary system gone over the world?" he gives the reply that the ablest men in the profession have chosen to work within the walls of voluntary institutions from which "almost every addition" to medical knowledge has come. Further extolling the virtues of the voluntary hospital, Lord Moran observed that it had a personality of its own which "stirs up around it a spirit of service." If they lost the local interest they would lose something of great value, not only to the hospital but to the community. The work of the voluntary hospitals had been the expression in peace of the altruism of war. Coming to the composition of the regional boards, he believed that their members should be hand-picked, and he hoped that information on this point would be forthcoming. He summed up many professional apprehensions in this observation: "I can only envy the Minister in his ready assurance, gained in the few hours he can take off from housing, that by turning a profession upside down he will necessarily provide a better service for the people."

The spirit of voluntary hospitals and the importance of local enthusiasm and loyalties were stressed by other speakers, and there was agreement with Lord Inman's view that waste should be eliminated and that financial obstacles should be removed: he did not see why voluntary support should not continue. Lord Donoughmore deplored the division of the hospitals into two systems, applauded the government of the voluntary hospital by the elected board working in harmony with a medical committee, and doubted whether the medical superintendent of a municipal hospital was a wise substitute for the medical committee. He made the interesting observation that one of the important municipalities in the Midlands has abolished the post of medical superintendent and established a medical committee in one of its hospitals. This, it seems to us, is a pointer to a reform of the municipal hospitals which would remove nine-tenths of the professional objection to them. Lord Donoughmore expressed his alarm at an advertisement in the *Hospital*, in which the Ministry of Health invited applications for posts as "nursing officers," the applicants being warned that they might have to live in any one of ten cities in England. Were these officers going to work under the regional boards or under the Ministry of Health independently of them? Lord Luke, agreeing that there must be some co-ordination of the health services, asked whether it was wise "completely to standardize when at the present moment we have variety." He thought that the voluntary hospitals might be dealt with in the same way as the voluntary schools. The White Paper proposals aimed at legislating out of our country local interest

and pride "for the sake of tidiness in a great scheme for the sake of very remote control." While they had heard much about the endowments which were to be taken over from the hospitals—the figure mentioned was £32,000,000—they had not heard so much about the value of the buildings, equipment, and land also to be transferred. The total value of what it was proposed to take over from the voluntary hospitals was in the nature of £250,000,000. Lord Luke felt that a Government Bill should be framed to encourage all that is best in the existing structure, and not to destroy everything and start from scratch "with a lot of disgruntled people." Lord Horder in a brief speech, thought that Lord Moran had somewhat expanded the wording of his motion, and contented himself with quoting the statements made by the King's Fund and the British Hospitals Association, and in the leading article published in the *Journal* of April 13 (p. 575).

In replying for the Government Lord Listowel said it would be a mistake for the Government to lay down in advance the exact constitution of the Regional Boards because their size and composition would vary according to the needs of the different areas. The boards would consist of people chosen for their individual suitability, not as delegates or representatives of different and possibly conflicting interests in the area. It was extremely unlikely that on any board any one element or interest would be in a position to obtain a clear majority by outnumbering the others. The letters in the *Times* suggesting a larger measure of independence for local management committees would be bound to command respect. For the future administration of the hospitals the Government would aim at securing the maximum amount of devolution and local independence within the regional framework. "Decentralization is itself the goal, and no more central control is wanted than an efficient and co-ordinated service necessitates." Both Regional Boards and Management Committees would have "unfettered financial freedom within the limits of their annual budget." There would be no Treasury interference in the detailed allocation of this. One of the main objects of the Bill was to provide a planned and co-ordinated hospital and specialist service, and this would be defeated if the new services were broken up into isolated and disconnected units.

As the above summary shows, the debate was centred mainly on the hospital service, but a number of speakers also made observations on the White Paper proposals for a general practitioner service. Lord Moran, for example, was satisfied that there was "fairly general disquiet among practitioners about the future." The principal reason for this was the dread that the proposals might lead to a whole-time service. He thought that the life of a general practitioner during recent years had lost something of its colour because he had seen treatment of serious disease pass into the hospitals and out of his hands. Lord Geddes said he felt strongly about the future scheme for general practice. He did not think that the "polyclinics . . . called health centres" would make for confidence between patient and doctor. He could well imagine a man or a woman being unwilling to go to such a centre because of the recording of some malady "on some bit of paper which would pass

through the hands of some not very responsible clerk." He observed that the secretarial service would be provided by the authority owning the centre. If there was something in the organization of the centre which would make the patient feel it was not safe to go to it, harm would be done. Was it not possible instead to provide diagnostic centres? He hoped that when the series of proposals had passed through the necessary stages before becoming the law of the land it would be found that "we are dealing with a medical service in this case, and not with a thing mis-called health service." Lord Piercy, on the contrary, thought that under the new conditions the life of the ordinary doctor would become more interesting and stimulating than it is now. The mass of the population at the moment had to choose between "very inferior doctoring and the out-patient departments of hospitals. The doctoring is inferior and perfunctory because it is under the panel system." He criticized what he called the present condition of private entrepreneurship. Lord Listowel considered there was misunderstanding about the powers of the proposed medical practices committee. This would have no power to direct a practitioner into a particular practice. The function of the committee was negative rather than positive. It would, in fact, be performing the functions of an appointments board or employment agency. It had power to refuse a doctor admittance to certain parts of the country, but there was the safeguard that a doctor whose application was refused had a right of appeal to the Minister.

Many useful facts and opinions came out of the Lords debate, in which slogans and gladiatorial displays were conspicuously avoided. But the temperature of debate is likely to rise in the Commons. Letters to this *Journal* show that medical men dislike the general tenour of the Bill, and constructive criticisms will no doubt emerge at the Special Representative Meeting next week.

PASTEURIZATION DEFERRED

The House of Lords continues to show a lively interest in health matters, and in a debate a fortnight ago brought to the fore the difficulties of providing the people of this country with a sufficiency of safe milk. In a maiden speech Lord Rothschild "rose to call the attention of His Majesty's Government to the urgent need for the compulsory pasteurization of milk in as many parts of the United Kingdom as is practicable"—a motion which Lord Ammon subsequently said the Government was prepared to accept. Lord Rothschild put the yearly number of deaths from drinking tuberculous milk at 1,600, and the number of casualties at between 7,000 and 8,000—casualties which required "months of hospital treatment and were a source of misery and anxiety to their families and great expense to the State." He referred also to other milk-borne infections, such as undulant fever, enteric fever, dysentery, food-poisoning, scarlet fever, and diphtheria. He discounted the objection that pasteurized milk has an unpleasant taste; and to the objection that pasteurization takes "the life" out of milk he remarked it was true that heat treatment did take the life out of the noxious bacteria so often

present in it, although he doubted whether those who put forward such statements meant them in this sense. The view that destroying noxious germs would prevent the population from acquiring a natural immunity to disease was one which he thought would not appeal to the mothers of children who have died from bovine tuberculosis. And he went on to ask why we did not drink water contaminated with the germs of enteric fever. Lord Rothschild proposed that compulsory pasteurization should be instituted in towns of more than 20,000 inhabitants.

Lord De La Warr, speaking from the agriculturist's point of view, said that it was for them, as producers, to supply the nation with the milk the medical profession said would be best for the national health. He drew attention to the position of the producer-retailers. There were about 50,000 of these in the country, and they handled about 20% of the milk supplied, mostly for small or urban communities or rural communities outside the range of the large distributor. If the Government tried to quicken the pace of cleaning up the milk supply delivered by this section of the trade the effect might be to drive these men out of business and so deprive the community of a large quantity of milk. He therefore considered that they should tackle the problem of cleaning up the herds and the farms of the producer-retailer, and, in their case, "provided that the milk is clean I can see no very great reason for pasteurization at all."

Lord Bledisloe, speaking with wide knowledge of the whole subject of milk, observed that the main advantage of improving the health of dairy cattle was to increase the yield of milk. The milk yield of a cow in this country was less than 500 gallons a year during the lactation period, as compared with 750 to 800 gallons in countries like Denmark, Finland, and Holland; and the consumption per head per day was less than that in most civilized European countries. Although 40% of the country's cattle reacted to the tuberculin test, they should, he said, at the same time remember that only one-half per cent. of dairy cattle yielded tuberculous milk. He agreed with Lord De La Warr that pasteurization was not an alternative to the improvement of animal health, but complementary to it. He thought that the opposition of some stock-owners to pasteurization would disappear if the Government would give a firm assurance that they would actively promote improvement in the health of dairy cattle as well as insist upon the pasteurization of milk so far as that was practicable. In view of the shortage of reliable pasteurization plant and of trained technical staff, he believed there was strong justification for "allowing the best milk produced on our British farms to be delivered raw to the consumer, at any rate for the present." Again, he observed that "the soundest practical measure would be compulsory pasteurization of all milk except that coming from tuberculosis-free herds and so far as practicable from herds free from contagious abortion." He also pleaded for the strengthening of the veterinary profession.

Lord Ammon said that of the annual consumption of liquid milk in England and Wales, amounting to about 1,075 million gallons, approximately 725 million were already heat treated. Of the 350 million gallons not heat-

treated about 190 millions were sold by producer-retailers, and the quantity of this up to T.T. standard was about 18 million gallons. A census carried out in 1943 in grant-aided schools and private schools participating in the milk-in-schools scheme showed that 67% of liquid milk supplied to 30,000 schools was heat-treated milk, 6.4% was T.T. milk, and the remainder accredited or non-designated raw milk. Lord Addison drew attention to the fact that the water supply to vast numbers of our farms was most inadequate, and that many of them had no electric supply. In some parts of the country it was not easy to find a farm with a well-equipped and properly constructed cowshed. They had an immense expenditure in front of them in effecting improvements in farm buildings.

In the *Journal* of March 9 we published a table showing the death rates from abdominal tuberculosis between 1921 and 1944 in children under 5 years of age in London, county boroughs, urban districts, and rural districts. For comparative purposes these deaths give the best indication of the prevalence of bovine disease. The figures, supplied by the Registrar-General, show that the death rates have continuously declined in each year. The figures showed that in 1944 the rate for London was only one-tenth of that in rural districts, and that, compared with 1921, the 1944 rate in London was one-twenty-third, and that of the rural districts one-quarter. In other words, the decline in London has been much steeper than that in rural districts. The actual numbers of deaths in 1944 were: London 1, county boroughs 32, urban districts 42, and rural districts 37. By 1938 we may observe that in London over 98% of the milk was pasteurized, and in county boroughs over 50%. It seems undeniable, therefore, that pasteurization of milk is an important factor in controlling the incidence of mortality from bovine tuberculosis, and that the protection of the interests of the small producer-retailers means a lack of protection for the health of those who consume the milk supplied by them. If at short notice under stress we can train technicians and produce equipment for killing other people with explosives, it seems anomalous that the production of pasteurization machinery and the training of technicians should seem to be such an insuperable obstacle in the way of pasteurizing all the milk consumed in this country until that time when we can be sure of drinking milk made safe by other methods.

COBRA VENOM FOR ANGINA PECTORIS

Sublingual nitroglycerin is now generally accepted as the best drug for the relief of angina pectoris, but in cases refractory to nitroglycerin the claims made for any other beneficial drug deserve consideration. Freedberg and Riseman,¹ for instance, find that cobra venom has a limited value in refractory cases, although it is less effective than nitroglycerin in patients who responded to both drugs. In three out of five who benefited from none of the usual remedies, including nitroglycerin, cobra venom diminished the frequency of the attacks and increased the exercise tolerance. In contrast to nitroglycerin, which causes coronary vasodilatation and relieves pain by relieving

ischaemia, cobra venom has an analgesic effect which masks the pain of myocardial ischaemia. The analgesic effect, with its permissive increase in exercise tolerance, may give a freedom which is bought too dearly at the cost of increased myocardial ischaemia. The high cost is shown well in an electrocardiogram of one patient in whom a standard amount of exercise caused a depression of the ST segment and anginal pain; when sublingual nitroglycerin was given the exercise caused no ST depression and no pain; after a course of injections of cobra venom the same amount of exercise produced the ST depression, but there was no pain.

Refractory angina may demand a desperate remedy, but this seems not just to black-out the warning light but to screw down the safety valve. Other serious objections to venom are its delayed action, the lack of maintenance of effect after a few weeks, and the suggestion from the data that the toxic dose may be only a little more than the therapeutic one.

PENICILLIN AND DIPHTHERIA

In view of the success of penicillin in the treatment of so many different infections, and of the statements sometimes made that the diphtheria bacillus is comparatively sensitive to penicillin *in vitro*, many doctors may have wondered whether penicillin might not be used with advantage for the treatment of clinical diphtheria as an adjunct to, or a substitute for, antitoxin. This possibility has recently been investigated by Ercoli, Lewis, and Moench.¹ They confirmed that the growth of the bacilli *in vitro* is inhibited by penicillin in concentrations of just over 1 unit per ml.: although this is 100 times more than is required to inhibit the growth of haemolytic streptococcus, the effective concentration is not unduly high. The lesions of diphtheria, as they occur in man, can be analysed into a small component due to actual multiplication of the bacteria in the body, and a large component due to the absorption of toxin. An experimental bacteriaemic infection can be produced by injecting the bacilli intraperitoneally in mice together with mucin, which handicaps the defence mechanisms of the host; this type of bacteriaemia due to diphtheria bacilli is readily prevented or cured by subcutaneous injections of penicillin or by the oral administration of sulphadiazine, while antitoxin has little effect on it. On the other hand, if diphtheria toxin is injected subcutaneously into rabbits or guinea-pigs, penicillin even in high doses has little or no action in preventing the typical lesions. When a small inoculum of bacilli is injected into guinea-pigs, the course of the infection resembles that in man—that is, there is only limited multiplication of the organisms but the animals die from the toxin produced. In this case penicillin has only negligible action. Arguing by analogy from these experiments, it may be concluded that, though penicillin might possibly be slightly beneficial in prophylaxis for exposed contacts (to prevent multiplication of bacteria), it would have no appreciable value for the treatment of patients with established diphtheria. For these cases, which constitute the vast majority of those which are encountered, nothing should delay the early and ample administration of antitoxin.

We regret to announce the death of Sir Harold Stile, emeritus professor of clinical surgery in the University of Edinburgh and consulting surgeon to the Royal Infirmary.

APPARATUS AND ROUTINE FOR DIABETIC WARD-TESTS

BY

TREVOR C. BEARD, M.B., B.Chir.

Former R.M.O., Hertford County Hospital

Most authorities who believe that a high blood sugar (even in the absence of ketosis) is harmful to the diabetic ask for a multitude of tests, which, in a hospital devoid of "student-labour," are apt to encroach severely on the nurses' and house-physician's time. The following routine was adopted at this hospital from the method in use at St. Bartholomew's and has led to great economy of effort. The method of three-hourly tests is that advocated by Dr. George Graham, and the chart is a modification of his. I am indebted to him for his advice and permission to submit these details for publication.

Use of the Apparatus

The urine-testing room of each ward is provided with a waterbath which takes four numbered test-tube racks, the holes of which are stamped with the times of the urine tests. A 5-ml. automatic burette is also provided. This can be bought, if the need is anticipated, about twelve months in advance, but it can easily be made and calibrated in one hour from standard laboratory components and fixed to the reagent-cup-board by spring clips, or placed on a stand. In each ward the following notices are displayed

FIG. 1.—Tube B is a 2-inch (5-cm) length cut from a thick-walled test-tube; the spring clips attaching it to the cup-board are not drawn. The supply is by siphon from a winchester bottle on top of the cup-board. When Clip 1 is opened the reagent floods the apparatus and overflows into the thistle funnel, leaving an air-lock in the upper part of Tube B. When this clip is released and Clip 2 is opened the contents of Tube A, Tube B, and the vertical limb of the T-piece are delivered. The overflow is collected in a small bottle and returned to the winchester from time to time. By vertical adjustment of Tube A the size of the air-lock may be varied until the volume delivered is 5 ml.

time the specimen was taken; 5 ml. of Benedict's reagent should then be added from the automatic burette. When a specimen is unobtainable it is safest to remove the corresponding tube from the rack. At the appointed time see that the water boils actively for at least five minutes, then record the results on the patient's chart at once.

Unless specially requested, the 12 midnight and 3 a.m. specimens are not required, but (1) any specimen which may be passed should be tested; (2) two specimens should be tested before breakfast. To fulfil this requirement some patients have to be awakened at 3 a.m.)

Tests for Ketones.—Test every specimen for ketones until these instructions are modified by the house-physician. If Rothera's test is positive, use the ferric chloride test as well (provided the patient is not taking salicylates in any medicine). Record on the patient's chart either a dash (—) or the letter R if Rothera's is positive, or the letter F if both are positive. [Details of Rothera's and the ferric chloride tests are then given.]

If these instructions are followed, time is saved in several ways. All labels, for example, are dispensed with; the times on the rack-holes identify the test-tubes, and the number at the end of the rack identifies the patient. The time-consuming mistake of filling numerous test-tubes with unmeasured specimens is also avoided. The difficulty of distinguishing a tube containing only 8 drops (the right quantity) from one which is merely wet is dealt with by adding the Benedict's at the time of putting up the specimen.

The "appointed time" of boiling the waterbath is a matter of choice. By the second day after admission the information given by a mass test once in twenty-four hours is sufficient to balance most cases. Although the ideal time for this would be at the end of the diabetic day (7 a.m.) it is quite satisfactory if the boiling of all the specimens is delayed until the morning round. The dose for the evening and the following morning is then prescribed. If at any time a patient's condition changes unexpectedly, the "story so far" can always be obtained within ten to fifteen minutes by lighting the bath, and this need not interfere in any way with the rest of the tests.

Method of Recording

A chart is used which gives a graphic representation of the diabetic day, and which has proved itself in practice. Fig. 2 shows only one of the five days which are represented on each quarto-size chart. One might suppose that the asymmetrical change of date would be confusing in an essentially practical chart, but it has been found unexpectedly convenient, starting as it does at the time the day-staff comes on duty. All the (diabetic) prescribing is done on this chart. The carbohydrate

FIG 2

can be written in grammes or in Lawrence's "black lines" (tens of grammes), if these are used. If extra carbohydrate has to be given in the form of glucose, this can be graphed and seen in perspective, as it were, when prescribing for the next day. The carbohydrate line lends itself readily to the straightening of "peaks" of glycosuria, such as occur when changing from soluble to protamine-zinc-insulin. The main advantage of the chart as a whole is that every detail relevant to the case is presented on the same piece of paper in its proper time-interval. This not only is convenient to the physician but also helps the patient to understand what is happening. The patient sees his "sugar rising and falling," and the insulin on one side "pulling it down" and the carbohydrate on the other "pulling it up." Just above the highest line for glycosuria is the horizontal column for the topmost calamity—ketonuria. In this disease, in which self-knowledge is of the utmost value to the patient, the use of a graph saves many words of explanation.

In closing I must thank Dr. Geoffrey Evans of St. Bartholomew's Hospital for his encouragement at all times and in the construction of the devices when I was his house-physician; also Sister Harvey, Dr. Gregson Williams, Dr. Brian Stanley, Dr. E. M. Dimock, and the sisters at Hertford for their assistance and advice.

The waterbath can be obtained in stainless steel from Messrs. David Allan, of 119, Haggerston Road, London, E.2, and the charts are printed in an attractive "ledger-ruled" by Messrs. Simpson, Shand and Co., Hertford.

HOSPITAL APPOINTMENTS FOR DEMOBILIZED M.O.s

It has been brought to the notice of the B.M.A. that there has been some misunderstanding of the position concerning resident hospital appointments for demobilized medical officers who have not been approved for appointment to B1 posts in Class I or Class III of the Government's postgraduate training scheme. It is not the case that all B1 vacancies are reserved for candidates approved under the scheme and that other demobilized doctors have no opportunity of obtaining such posts. It is true that a hospital making an appointment outside the scheme cannot obtain a grant for the purpose of raising the normal salary of the post to the amount provided under the scheme when it is less than that amount. It is true also that a post supernumerary to the approved wartime establishment of a hospital cannot be created except for the benefit of a practitioner entitled to an appointment within the scheme. But there is no question of a ban on applications from other demobilized doctors for advertised vacancies.

TRAVELLING FELLOWSHIPS IN MEDICINE

The Medical Research Council invites applications for the following Travelling Fellowships for the academic year 1946-7.

Rockefeller Medical Fellowships

These Fellowships are provided from a fund with which the Council has been entrusted by the Rockefeller Foundation of New York. They are intended for graduates resident in this country who have had some training in research work in clinical medicine or surgery, or in some other branch of medical science, and who are likely to profit by a period of work at a centre in the United States or elsewhere abroad, before taking up positions for higher teaching or research in the United Kingdom. The stipend will ordinarily be at the rate of £450 per annum for a single Fellow and of £650 per annum for a married Fellow. Travelling expenses and some other allowances will be paid in addition.

Research Fellowships in Tuberculosis

Dorothy Temple Cross research Fellowships in tuberculosis are awarded by the Medical Research Council from a special endowment of which its members are the trustees. The object of the Fellowships, as defined in the Trust Deed, is to give special opportunities for study or research to suitably qualified British subjects of either sex "intending to devote themselves to the advancement by teaching or research of curative or preventive treatment of tuberculosis in all or any of its forms." The Fellowships will, as a rule, be awarded to candidates who wish to make their studies or inquiries elsewhere than in the United Kingdom. They will ordinarily be awarded for one academic year. The Fellowships provide for the payment of stipend, together with an allowance for travelling and incidental expenses. The stipend will ordinarily be at the rate of £450 per annum for a single Fellow, and of £650 per annum for a married Fellow.

Completed applications for Fellowships of either type must be lodged with the Council not later than June 1, 1946. Further particulars and forms of application are obtainable from the Secretary, Medical Research Council, 38, Old Queen Street, Westminster, S.W.1.

Nova et Vetera

A COMMEMORATION AT BART'S

400TH ANNIVERSARY OF THE SECOND FOUNDATION

St. Bartholomew's Hospital has now been in existence for 823 years. It was founded by Rahere in the reign of King Henry I in 1123. It passed through a very severe and almost fatal crisis in the sixteenth century. About the year 1539 King Henry VIII took unto himself lands, rents, and perquisites longed to the hospital because of its connexion with the glory of St. Bartholomew the Great. Without going into detail, such was the parlous condition of the hospital's finances that in 1546 the Mayor, Commonalty, and citizens of London petitioned His Majesty for the restoration of the rights, privileges, and revenues of the said hospital, and on Dec. 27, 1546, Henry VIII granted the petition by "letters patent," thereby restoring the income of the institution and placing the governance of the hospital in the hands of the City Corporation. Henry was at that time a very sick man, and he died one month later.

This year, 1946, is also the anniversary of several other points in the history of St. Bartholomew's Hospital. It is the 150th anniversary of the formation of the Abernethian Society, which has commemorated that great surgeon of the hospital in this manner. It is the centenary of the introduction of chloroform for use as an anaesthetic in the hospital. It is the jubilee of the first use of x rays in diagnosis.

It has been decided to commemorate the second foundation of the hospital 400 years ago on Wednesday, May 8, which date is also the first anniversary of victory in Europe—VE-Day. The old Priory Church of St. Bartholomew the Great is to be used as a setting for some episodes in the history of the hospital and for a commemoration service. A procession will leave the hospital at 11.35 a.m. and will be met at the gateway of the church by a procession of clergy. All attending will be in their seats by 11.45, soon after which the King and Queen will arrive to honour the commemoration with their presence.

Mr. W. McAdam Eccles, senior consulting surgeon to the hospital, has taken an active part in the arrangements for the commemoration, which include a reception in the hospital square and an address on the history of Bart's in the afternoon. It is also hoped that there will be a historical exhibition from 10 a.m. to 5 p.m. on Tuesday, Wednesday, and Thursday of that week. Any inquiries should be addressed to the hon. secretary of the Commemoration, St. Bartholomew's Hospital, London, E.C.1.

Correspondence

The Health Service Bill

SIR,—May I plead, even now, that every member of the profession should take the trouble to read the unabridged Bill itself before undertaking to approve or criticize it? We are supposed to be a learned profession, yet how many of us behaved like educated beings and made the effort to read the Bill and digest it before discussing it? Your correspondent Dr. A. A. Vickers (April 13, p. 584) is generous to assume that speakers who uttered misleading statements had "misread" the Bill; more probably they had not even seen it. At a recent meeting of all practitioners in this district it was indeed "nauseating" (to quote Dr. Vickers) to observe how ill informed several speakers were. Some had not even read the over-optimistic "Summary"; others had swallowed the whole thing—"hook, line, and sinker." (Because it called itself a "Bill for a National Health Service" therefore it must be good.)

I am sure, myself, that if every doctor reads this Bill complete, he will realize with growing understanding just what it is that it sets out to achieve: not to achieve an improved medical service (the B.M.A. has been pressing this for years unheeded); but to ensure total control of both doctors and hospitals. Every "doctor" worthy of the term wishes to improve the services rendered to his patients, but this Bill does not even pretend to do so. It is nationalization from first to last, and what is to happen when once this is achieved is nobody's business.

Finally, here are two practical suggestions. First, let the B.M.A. at once produce an *accurate* summary of the Bill, designed to show how much of it is concerned with improvement of service and how much with control or finance. Secondly, let every member of the profession obtain for himself a copy of the Bill and make it his business to master its contents. He will then be able to discuss it intelligently.—I am, etc.,

Dartford.

G. F. TRIPP.

SIR,—If we are to have much hope of improving the National Health Service Bill the pressure must come eventually from the people and not from the doctors. So far the B.M.A. has failed to impress public opinion, largely because the Council has, quite rightly, been engaged mainly in discovering how far the various provisions in the Bill agree with or differ from the broad Principles laid down. In practice I find that the implications of these Principles are not understood by many doctors, while to the general public they are *unintelligible*. Emphasis on them merely serves to convince the public that this is, as many papers try to suggest, just a quarrel between the doctors and the Government and that it does not affect the public intimately. I believe that if our influence is to have much effect we must go below the broad Principles to the *fundamental* issues underlying the Bill, and there, I think, we shall find material enough to interest and even excite many who are at present apathetic.

May I say at once that I write as one whose ideal has been that British medicine should be the best in the world, that it should be as fully available as possible to everyone, and that it should be available without fear of doctors' bills. Yet I find myself utterly opposed to the present Bill for its methods and not its aims. What follows inevitably over-simplifies matters, but I believe that basically the statements are correct, and I hope that at the Special Representative Meeting on May 1 and 2 many of them will be discussed and clarified.

First of all, with the ostensible aim of abolishing doctors' bills, I find that the Bill contravenes nearly every principle for which trade unions have fought for the past half-century: (1) Freely negotiated settlements. (2) Good and acceptable

conditions for workers. (3) Removal of economic pressure. (4) Removal of the threat of Government pressure (cf. the repeal of the Trade Disputes Act). (5) Liberty of the worker to choose his job, to offer his service to whom he will, to choose his place of residence, and to benefit from the results of his labour.

This country has just fought a war to vindicate the rule of law instead of the rule of force in international affairs, yet this Bill is founded on the use of force and its twin brother confiscation. The forcible taking over by the Minister of all hospitals and their endowments is an act of confiscation only to be paralleled in British history by the Dissolution of the Monasteries, and without any of the justification there may have been for that measure. That the professed aim is to improve the hospital services should not blind us to this fact of confiscation, and the further fact that it would form a precedent for the sequestration by the Government of any and every private benefaction, even the National Trust itself. Only the willing consent of all the governing bodies could make such an act lawful (I do not say legal), and this emphasizes that the future service must, in fact, be established voluntarily and not by the use of Government force.

My next trouble is that the Bill plainly aims to establish a State monopoly for medicine in spite of a few fair words about private practice, for it creates conditions in which such practice cannot do anything but languish. Now a monopoly of medicine is the worst of all State monopolies, except perhaps of religion, for it affects the whole man—body, mind, and largely spirit too—while other monopolies affect but one aspect of his physical or intellectual life. Such a monopoly we and the public must resist to the utmost.

The main urge for a national medical service seems to derive from Assumption B of the Beveridge report, which stressed, among other things, the necessity for improved control of certification. The Bill makes only one small reference to certification (Clause 33 (2) (d)), for all the rules are to be laid down by regulations of the Minister. As sickness absence is now about twice the pre-war level, mostly, I believe, justifiable, and the Social Security Bill allows for only a 20% increase, it does not need much imagination to visualize what sort of regulations these will have to be to close the 80% gap. The welcome return of some millions of healthy workers will, of course, tend to diminish this figure, but the effects of war strain and the re-employment of married women may largely offset this advantage.

That these fears are not groundless is shown by the following fact. In a Bill marked by extraordinary vagueness in nearly every part there is one clause which is full and explicit in every detail—that concerning the prohibition of the sale of practices. The whole clause is worthy of serious study, but I quote one passage only: "... proceedings for an offence under this section may be brought either within one year from the date of the commission of the alleged offence or within three months from the date on which evidence sufficient in the opinion of the Minister to justify a prosecution for the offence comes to his knowledge, and for the purposes of this subsection a certificate purported to be signed by the Minister as to the date on which such evidence as aforesaid came to his knowledge shall be conclusive knowledge thereof." Note the last few words; there is no security for the individual except the long process of the law, but the statement of the executive may not be checked or questioned. This is a sample of the regulations that may be expected from the Minister, which, indeed, many of us would expect from this Minister, and if the doctors and the public accept the Bill in its present form we have said good-bye to the freedom of the profession and the liberty of the subject. I believe that all the purported aims of this Bill could be obtained much better by co-operation than by compulsion and at less cost, and we must always remember that the exercise of ordered freedom is an essential part of health, of communities as well as individuals.—I am, etc.,

Winsford, Cheshire.

W. N. LEAK.

SIR,—The B.M.A. statement on the National Health Service Bill, Dr. Hill's recent speeches, and much of the correspondence on the same subject oppose the Bill mainly on the grounds that it introduces a salaried State service. I have just spent six years in the R.A.M.C., which is a salaried State service,

and while like most officers I found much to criticize, there was also much that was good, in particular the absence of the monetary relationship with patients, which gave a feeling of freedom in treatment never experienced in general practice before the war. It seems to me that the objections advanced against a salaried service have not as much weight as is commonly attributed to them. There appear to be four main ones, to all of which counter-arguments can be offered.

(1) Loss of incentive.—Pursued to its logical conclusion this argument means that the private patient receives more attention than the panel patient, a suggestion which is always vehemently repudiated. Does not a general practitioner increase his income just as often by buying an extra share as by increasing the number of his patients? Is it not true that usually our work occupies our time so completely that any substantial increase is impossible? Loss of incentive is not a necessary accompaniment of all salaried services. Why should it be so in medicine?

(2) Loss of patient-doctor relationship.—(a) Choice of doctor; is not this a limited privilege even at present? And how often is the choice exercised by change of doctor? Need a salaried service, then, exclude all choice of doctor? (b) Certification; the objection that this would be exercised in the interest of the State and not of the patient is a slur on our professional integrity which is unwarranted. Even in the Army, where the primary object is admittedly the efficiency of the service, it is still possible for a medical officer to look after the interests of his men and be trusted by them. Furthermore, would not this objection with regard to certification apply equally in a service remunerated by capitation fee?

(3) Loss of professional freedom and responsibility.—On my Army experience again I would say that this does not necessarily follow; I certainly never found it so.

(4) Direction.—The proposals in the Bill for distribution of practices are complicated and unpleasant. Direction exists, of course, at present based on demand and supply. Could not this be continued by advertisement in the journals of vacancies as they occur in the various areas, application being made to local medical committees, who would then fill the appointments? Similar provisions could be made for assistants.

For my part, then, I feel that opposition to a National Health Service should not be based mainly on the grounds that it introduces—immediately or remotely—a salaried State service. In fact I would suggest that it is opposition on these lines which has led to the much more unsatisfactory proposal in the present Bill for the payment of general practitioners. There are, however, many other points in the Bill, apart from those related to this question of salary, which would detract from the efficiency of the service whether salaried or not, and which must be strongly opposed. They have already been indicated in the B.M.A. circular and in the journals; the most important are: organization and administration as three separate services; local government (clinic, domiciliary, and welfare) services; family practitioner service: health centres, status of assistants, distribution of practices. I suggest that action to amend these points is much more important, will command greater support, and be more likely to be successful than opposition based on objection to a salaried service.—I am, etc.,

Neston, Cheshire.

K. COBBAN.

SIR,—One of the dangers of the National Health Service Bill is that it may lead to the complete split of the general practitioners into two groups: those employed by the State and those employed privately. Admittedly the Bill states that private practice will be permitted for those joining the service, but a principle is involved here which has received far too little attention. Many doctors think that because they do private and panel practice now, it will be equally reasonable for them to do private and State practice in the future. They forget that panel practice is limited to those under a certain income; and that doctors who agree to do panel work should attend those patients who are entitled to the panel in the scheme and not outside it. In the new Government service there will be no income limits, and therefore if doctors choose to join it they should attend their patients under the terms of the service and not follow the bad principle of attending them outside it for a private fee.

From a political point of view it may be desirable to create a new type of general practitioner—i.e., one who is paid by

the State and is under its control, and from whom anyone could obtain free treatment. From a medical point of view it is an unwise step to take at present, for it will lead to a relative shortage of doctors, since the majority of them now do both panel and private practice.—I am, etc.,

London, W 8.

H. STEPHEN PASMORE.

SIR,—The report (April 6, p. 535) of the excellent address by Dr. Guy Dain to the meeting of Bournemouth practitioners contained a misprint, or else Dr. Dain made a most serious error. He referred to a population of over 40,000,000. In the National Insurance Bill, 1946 (Report by the Government Actuary on the Financial Provisions of the Bill, page II, Table V), the population is given as 48,200,000. The importance of this figure is, of course, in connexion with remuneration. The estimated remuneration for the G.P.s, chemists, dentists, and supplementary eye services is £45 million (National Health Service Bill, page III)—that is, 18s. 8d. per head per annum, or 4.3d. per person per week for the four services.

What proportion of this will the general practitioner get? Would one be far wrong in saying that it will be £30 million for the doctors and chemists (as proposed in the Coalition White Paper of February, 1944) and £15 million for the dentists and ophthalmic services? Dividing the £30 million in the proportion now obtaining in the present N.H.I. scheme would give £23½ million to the general practitioners and £6½ million to the chemists. The sum of £23½ million represents for 48,200,000 people a capitation fee of 9s. 9d. per annum or 2½d. per week, by whatever method it may be paid. As a comparison I would take the National Insurance Bill, 1946 (p. 7), where the cost of administration is given for employed men and women as 5.0d. per week, whereas the general practitioner is offered less than half this amount and out of that has to pay all his expenses—surgery, equipment, clerical, postages, telephones, motor-car, and locumtenent during holidays and illnesses. May I also point out that the service contemplated in the Bill is a 24-hour-a-day service, 7 days a week, 365 days a year.

By all means let us fight for Principles, but let us not forget that we cannot live on Principles, and that it is high time that the report of the Spens Committee was forthcoming, with the Ministry of Health pronouncement on that report, so that we know exactly where we stand.

May I emphasize what Dr. Nigel Cridland said in his letter (p. 541) and recommend that every member of the profession should read the Bill itself and not the highly glossed and polished summary—I am, etc.,

RhyJ

J. G. MACQUEEN.

SIR,—I attended the meeting in Wimbledon and heard Dr. Hill's magnificent exposition of the Bill; but while I am 100% opposed to it, as thousands of other doctors are, I feel we, as a profession, are being destructive and not constructive. Some reconstruction is necessary, but what proposals have you put forward by our profession as a whole? As I pointed out in a previous letter, once the Bill such as now drafted comes into force the doctor—whether G.P. or specialist—becomes nothing more than a puppet of the State and his individuality and his personality are gone for ever.

The public do not want the Bill, the doctors do not want it, because both parties realize that "mass production" in medicine does not benefit the patient. If one associates outside one's own sphere to any extent the cries of the panel patient are heard long and loud in the wilderness, that because they are "panel patients" they don't get "good attention." How can they, when a G.P. can have a panel of 2,500 with a grandiose remuneration of 7s. 6d. (more now, granted) *per caput per annum*? Yet the proposed Bill makes the 40,000,000 inhabitants of Britain "panel patients."

Certain reforms are necessary, the main ones being the hospitals. One has merely to look at the "palaver" that is necessary to get a patient into hospital. A G.P., perhaps of 20 years' or more experience, wants to get a case of strangulated hernia admitted. He has to ring up the house-surgeon, who invariably is a young man just qualified, who questions the diagnosis, asks the pulse rate, and inquires if the patient is vomiting. After securing this information he goes away "to see if there is a bed," and it remains to his whim either to admit or to refuse admission to the patient. Such a state of things should not

prevail. A doctor with experience should not be cross-questioned on such details. He would not seek to get the patient admitted unless he considered it a hospital case. Let the State control the hospitals. The voluntary hospitals seem always in debt, and there exists little or no free hospital treatment to-day, because when a patient is admitted to a public ward an almoner appears and seeks to know the unfortunate patient's income, his outgoings and so on, and how much he can pay. Surely if a panel patient gets free treatment when at home he should get specialist treatment free in hospital.

I should like to put forward suggestions for modification of the Bill: (1) Hospitals to be taken over by the State and free treatment given to persons who avail themselves of the State service. (2) The panel system to be extended to persons with a salary not exceeding £750, with full liberty to "contract out" of the system if so desired on a basis of the "own arrangements scheme" at present prevailing. Persons with incomes over £750 to be permitted, if they so desire, to join the service. (3) The panel to be limited to 1,000 persons with a decent capitation fee—say, 15s. or £1 *per caput*. (4) Doctors to be free to join or resign from the State service. (5) Doctors to be permitted to do part-time State service and carry on their private practices independently. (6) Free sale and purchase of practices (private) to continue. (7) Where no central clinic is available doctors to get extra payment for the use of their surgery, etc., when compelled to see patients in their own houses. (8) Midwifery to be done by any practitioner and remunerated by the State.

The above are not meant to be comprehensive but a basis for a plan or scheme to be amplified and submitted to the Minister. We do not, as Dr. Hill says, want to talk about "striking," but this is the time in the history of our profession when, more than ever, unity is strength, and if our disunited profession will stand together in this hour of crisis—as Britain did in 1941—we can become victorious, knowing we are acting in the best interests of our profession and of the patients who rely on us to give our best to them.—I am, etc.,

CHARLES J. DE VERE SHORTT,
Barrister at Law.

London, E C

SIR,—As I left the meeting of my Branch, which had just approved by an overwhelming majority the Council's report, I overheard one member say to another: "The trouble with us is we can't trust each other." Cynical, perhaps, but how devastatingly true!

At this the most critical time in the long history of our profession we do not trust each other. The average man does not whole-heartedly trust the Negotiating Committee or the Council and the Representative Body of the B.M.A., though he is largely responsible for the constitution of these bodies. He thinks along these lines: "They let us down last time; they will let us down again. They will compromise and appease and in the end they will accept this Bill substantially as it stands. They have never got the better of any negotiations with any Minister of Health."

Surely the time has come to face the reality of the situation while there is yet time. Let us nail our colours to the mast: let us say, "We will not work this Act." Let us convince ourselves that we will fight. We shall then achieve that unity without which we must inevitably suffer defeat.—I am, etc.,

W. B. A. LEWIS,
President of the
Shropshire and Mid-Wales Branch, B.M.A.

SIR,—The following points in the Health Bill require serious consideration, and efforts should be made to have them modified.

Clause 18.—Blood for transfusion and any other substance or preparation not readily available in an emergency may be made available to general medical practitioners who require them in cases of emergency, "on such terms, including terms as to the payment of charges, as the Minister thinks fit." Surely to make a charge for anything (let alone blood for transfusion) for emergency and consequently life-saving treatment is not in the best interests of efficient medical treatment. These supplies are free to hospital and specialist services but must be paid for by the general practitioner.

Section 28.—(1) "A local authority shall make arrangements . . . for the care of persons suffering from illness. . . . (2) "

local health authority may, with approval of Minister, recover . . . charges from persons availing themselves of the services." We have here the position of, say, a husband developing pneumonia and being removed to hospital for treatment. A few days later his wife contracts the disease, but because there are no beds available in hospital she has to be treated at home. Circumstances require the local authority to help. Both recover, and if the man can afford it he has to pay for his wife's case at home; he was treated free in hospital. In other words, he has to pay for the fact that sufficient beds were not provided in hospital. The Minister evidently expects much remuneration from this section; otherwise it would not have been included. I suggest that para. (2) should be omitted from the Bill.

Section 42.—Reading the Bill, the only people from whom inefficiency is expected are those outside the hospital and specialist section, for only in respect of them is provision made for inquiry into their work and removal from the service. A tribunal of three persons is appointed which must inquire into complaints received from an Executive Council, and may inquire into complaints made by *any other person*. The offending doctor can be heard by the tribunal, and can appeal to the Minister and be heard by his representative. No provision is yet made for the accused: (1) to bring witnesses; (2) to question his accusers; (3) to be legally represented. Apparently there is no appeal from the decision of the Minister's representative. There is no appeal to the courts. The specialist services are in a much more favourable position, because no provision is made for inquiring into their work or dealing with complaints thereon from either official bodies or any other persons. As the Minister is to own the hospitals, he is certainly not going to provide for criticisms to be voiced.

Section 13.—The Regional Hospital Board and Boards of Governors, which control the specialist branch, although servants of the Crown, are expressly stated to be able to sue and be sued at law: "Shall be liable in respect of any liabilities incurred (including liability in tort)"—that is, wrongs against the person. This means that the specialist can sue these bodies for wrongful dismissal, breach of contract, and can question any of their decisions which cause him professional damage, and this can be done in the law courts with subsequent reinstatement and damages if the case goes in his favour. It is surely not too much to ask that these ordinary privileges of a British citizen should not be denied to general practitioners working the scheme.

The patient pays for the services but seems to have no say in what he wants; he is made to fit into the scheme. During the past week a notice was placed in my surgery stating that it was proposed in the new Bill that consultations should take place in a health centre. Patients were asked to express their opinion on this clause. Two books were provided: (a) for those who wished to attend a health centre; (b) for those who wish to continue as at present. The result is interesting: 136 wish to continue as at present and one wished to attend a health centre.

Regarding patients who remain outside the scheme of general medical services, are they to be permitted to take advantage of the "free" hospital-specialist services? The Minister has conceded one side of the arrangement, for he permits specialists to take private patients and treat them in hospital. A definite ruling on this point should be included in the Bill, for by denying them the hospital scheme indirect pressure could be exerted to force patients into the complete scheme. Patients remaining outside the scheme should be eligible for monetary benefits under the National Insurance Bill, and the certificates of their doctors, whether in the scheme or not, should be accepted for the purpose of securing this benefit.

Once the Bill is passed there will be very little hope of having any clauses altered; therefore arrangements should be made to try to modify or delete those which are undesirable.—I am, etc.,

Weybridge.

H. GORDON.

premiums, can be achieved with advantage to all interests. With reference to (1), civil law, the G.M.C., and professional and public opinion are safeguards proved adequate by time. With reference to (2), if we continue to give medical help to all who need it and at the same time refuse to give any form of certificate, the present proposals, together with the present contractual relations between doctors and insurance committees, would cease to prejudice the interests of patients, and details of a workable scheme could be arranged.

It is quite fallacious to think that the State would pay and should therefore have control. The State does not pay; the patient would and should pay. The State merely provides collecting and distributing services (for payment) as a matter of convenience; it has no title to domestic control of a purely personal and intimate relationship.—I am, etc.,

London, W C 1.

T. J. TAUNTON.

Postgraduate Medical Training

SIR.—On reading the description (April 13, p. 581) of the new British Postgraduate Medical Federation I am astounded to find that only a part of one sentence refers to the needs of general practitioners, while several hundred words are concerned with the training of specialists. In the statement of general policy to be followed, the teaching of specialists and specialist methods come first and second, respectively, while courses for general practitioners are only third on the list.

Why do we have all this emphasis on "new specialist institutes" and "special hospitals"? It is not difficult for the embryo consultant to get his postgraduate education. There are a number of posts in various hospitals which cater for him already. The man who needs all the help is the family doctor. As Osler said, "He still does the work; the consultants do the talking and writing, and take the fees." It is very hard not to get rusty in a busy general practice. Surely the primary aim of postgraduate training is to improve the professional standard of the ordinary doctor; to enable him to make use of all the recent advances in medicine and surgery; to bring to his notice those points which may have escaped him, busy in the routine of his practice.

After all, the great bulk of the medical work in this country is done by the general practitioner. This obvious fact seems to have been forgotten by those who drew up the policies of the new federation, whose organization makes it sound like a school for specialists. Education of the family doctor should be priority No. 1 on the list and not an afterthought. I wonder how many of those concerned with postgraduate teaching under this scheme will have knowledge or experience of the problems peculiar to general practice?

The other point which surprised me was the failure to mention the Fellowship of Medicine, which has been organizing postgraduate courses in London for a quarter of a century. This body has acquired a great deal of experience in dealing with the needs of doctors from all over the world. Among those who have conducted teaching under its auspices are several not without renown in the profession. It has always been able to give a great amount of information and advice on matters concerning postgraduate study in London to those who wished to know, and seemed superior to the British Postgraduate Medical School in this respect. Is all this fund of experience and knowledge to be ignored by the new federation? Let us hope that pride and jealousy will not prevent co-operation between the new and the old, for the benefit of the profession.

Finally, let us pray that the atmosphere of graduate teaching will not become too rarefied under the new order. Teaching of the specialties by the specialists for the specialists is all very well in its way, but what the country needs is better family doctors. The emphasis must be put in the right place.—I am, etc.,

Worthing.

TREVOR H. HOWELL.

Rapid Replenishment of the Circulation

SIR.—Anaesthetists, surgeons, and nursing staff have every reason to regard with misgivings the hospital's "no-man's-land"; that metaphorical entanglement with its icy blasts in winter, its lifts that are not always in working order, and, above all, its echoing void of almost everything that the patient—

SIR.—I would like to offer, for the consideration of my colleagues, two propositions: (1) There is no need for any interference by any person or body between doctor and patient. (2) If we refuse to enter into any form of contract except with the patient then a health service for all, paid by insurance

sometimes a patient hovering between life and death—may suddenly require. I refer to that variable space (variable with the intelligence exercised by those responsible for hospital construction) between the operating table and the patient's bed.

A woman of 50 had undergone the formidable operation of combined total cystectomy and total hysterectomy, for a growth of the urinary bladder invading the uterus. She left the operating theatre in good condition; nevertheless I had taken the precaution of placing a sternal marrow trocar and cannula in position in order that plasma might be administered by this route as soon as she had returned to the ward. In this particular case every convenient vein had been utilized for oft-repeated blood transfusions, rendered necessary because of haematuria. Suddenly, in the "no-man's-land" to which I have referred, she collapsed. Respirations had ceased except for an intermittent gasp, and the pulse at the wrist was imperceptible. Hastily summoned from the theatre and fearing that the suddenness of the untoward symptoms bespoke of cardiac arrest, I was contemplating pricking the ventricle when the anaesthetist, who had been summoned from the anaesthetic room, pronounced that he could detect a flicker in the carotid pulse. A courier dispatched to the ward for the plasma had not returned. A courier dispatched to the theatre for saline solution and apparatus was no doubt collecting the units. By a stroke of good fortune the highly efficient theatre sister (who was not on duty) appeared, and was able to produce from a stock-cupboard a bottle of saline and, thirty seconds later, a 20-ml. Record syringe and an enamel bowl. Using the syringe, I injected the saline solution into the bone marrow, and in under a minute my house-surgeon was alternating with me in the procedure with a second syringe he had fetched. In this manner we injected 1½ pints (700 ml.) in under three minutes with remarkable benefit, that happily proved to be the turning point in her recovery.

In surgical, and no doubt in gynaecological and obstetrical practice as well, there are crises where to be of value a pint or more of fluid must be put into the circulation in a matter of minutes. On such occasions, in my submission, injection of the fluid by means of a Record syringe or syringes into the bone marrow is a method that has yet to be bettered. By means of a sternal-puncture trocar and cannula the bone marrow can be entered with a swiftness and certainty that bedwarfs—nay, bepygmies—cannulization of a radicle of the venous system. I make this statement after a very full experience culled from years of special interest in the subject, and after watching assistants trained in many surgical centres of the Empire and the U.S.A. attempting to enter a vein of a collapsed patient.

To disarm those who may suggest that I have omitted the corpora cavernosa as a ready receptor, I would say that, for reasons that are fairly obvious, considerably more than 50% of those who need ultra-urgent fluid replacement are women, and that advocates of this route are agreed that it should not be used for electrolytic solutions. There is no contraindication to injecting isotonic solution into the bone marrow.—I am, etc.,

London, W 1

HAMILTON BAILEY.

"Congenital Malaria"

SIR,—Dr. I. G. Cameron (April 6, p. 544) questions the findings of Eckstein and Nixon¹ on the grounds that positive films were only obtained three weeks after birth. He does not note that, in these infants, the spleens were already two or three fingerbreadths below the costal margin.

During three years' work in Turkey, much of which was devoted to malaria surveys, I was able to satisfy myself that in infants a splenic enlargement of two or three fingerbreadths (due solely to malaria) indicated an infection of at least two months' duration.

Regarding Dr. Cameron's suggestion that the occurrence of true congenital malaria can only be finally confirmed by demonstrating the parasite immediately after birth, van Nitsen² records six children either born dead, or dying soon after birth, whose spleens contained malarial schizonts. In addition, Jones and Brown³ and Tanner and Hewlett⁴ recorded undoubted cases of congenital transmission in infants born in London.—I am, etc.,

British Postgraduate Medical School,
London, W.12.

R. F. JARRETT.

SIR,—I noted with great interest the "masterly touch" with which "Student No. 2" (April 13, p. 586) advanced his arguments on the problem of "congenital malaria" as presented by Profs. A. Eckstein and W. C. W. Nixon (March 23, p. 432). I do agree whole-heartedly with the plea put forward by him for a scientific investigation of the subject. The prospects of using the cephalin flocculation test as an aid in such an investigation do not seem to me to be very bright. In studying with Prof. E. W. Dennis the mechanism of the cephalin test (unpublished work), we found that this test is positive on cord blood obtained from 20 hospital cases, where the pregnancy, to the best of our knowledge, had been normal. The results were as follows:

Distribution of Cephalin Flocculation Reactions in 20 Specimens of Cord Blood from Normal Pregnancies

0	+	++	+++	++++
—	2	4	14	—

Why is it positive then? At what age does it become negative? Such questions can be answered only in the course of future research. The examination of blood films as a routine on newborn infants and their respective mothers does not seem to solve the problem, for a negative smear does not exclude the possibility of malarial infection. In the last laboratory meeting of the Royal Society of Tropical Medicine held in Liverpool on March 21 I had demonstrated an intradermal test in malaria (I.D.) prepared from chicken erythrocytes infected with *Plasmodium gallinaceum*. A control antigen was also prepared from normal chicken erythrocytes. Both antigens were tried on malarial as well as normal individuals. This antigen seems to possess a high degree of specificity. The mechanism of the test seems to be akin to that of the tuberculin test (O.T.) in tuberculosis. Detailed results will appear in the coming number of the *Journal of Tropical Medicine and Hygiene*.

This test, I believe, could be used to great advantage in indicating whether the tissues of the newborn are sensitized to this malarial antigen through a previous infection *in utero*. At the same time it could be used on pregnant women to distinguish malarial from non-malarial mothers, and on school-children as an index of malaria endemicity of the region to be selected for this investigation.—I am, etc.,

London, W.6.

J. G. MAKARI.

SIR,—I would be the last to assert that anything is "impossible," but I would like to say that I am in entire agreement with Dr. A. B. Raper and "Student No. 2" (April 13, p. 586). In malaria the incubation period, from the moment of the infected "bite" to the first appearance of symptoms, virtually connotes the multiplication of successive generations of parasites until they are sufficiently numerous to evoke a noticeable reaction in the tissues of the patient. May I suggest that in an infant a few days old this period is reached relatively early, depending largely upon the body weight as compared with that of an adult. I am afraid I should require much more convincing evidence than that produced by Profs. A. Eckstein and W. C. W. Nixon before I could be persuaded to believe in the antenatal transmission of malaria to an unborn child.—I am, etc.,

Brookwood, Surrey.

H. M. STANLEY TURNER.

Resistant Anaemia

SIR,—With reference to the article on resistant anaemia by Drs. A. H. Douthwaite and R. L. Waterfield (April 6, p. 519) I would like to make the following points.

In the first place, I am somewhat perplexed by the use of the word "resistant" as a classification of the anaemias. Does it mean resistant to diagnosis or resistant to wrong therapy? I personally feel that the term "resistant anaemia" (or more accurately "resistant cell anaemia") should be confined to those anaemias in which a proportion of the cells are unnaturally resistant to hypotonic salines, such as Mediterranean anaemia, sickle-cell anaemia, Cooley's anaemia, etc.—in fact, those anaemias which show exactly the opposite characteristics to acholuric jaundice when treated with varying dilutions of saline.

¹ Eckstein, A., and Nixon, W. C. W., *British Medical Journal*, 1946, 1, 432.

² Van Nitsen, *Ann. Soc. Belg. Mtd. trop.*, 1932, 12, 249.

³ Jones, J. L., and Brown, H. C., *Lancet*, 1924, 1, 1053.

⁴ Tanner, N. C., and Hewlett, P. F. L., *ibid.*, 1935, 2, 369.

In the second place I do not agree that chronic ulceration of the legs or the history of such ulcerations in association with anaemia is always due to acholuric jaundice. I have seen at least one example in a case of refractory normoblastic anaemia.

In the third place I am not convinced that a high colour index is a characteristic feature of the blood picture in acholuric jaundice. Whilst it certainly does occur, my impression is that it is usually about or below unity (*vide* Kracke).

In the fourth place may I protest against the use of initials in place of disease names in published work? Finally, I would like to point out that the differentiation of these two widely different diseases would solve itself if pernicious anaemia was never diagnosed without a confirmatory marrow smear in the stage of relapse when the two diseases could not possibly be confused—I am etc.

Diphtheria Immunization

SIR—May I clear up a misunderstanding. My letter (March 23, p. 445) was certainly never intended to suggest the conclusion drawn from it by Dr Grant—namely, that "full prophylaxis resulting in a Schick negative condition guarantees an immeasurably higher degree of immunity than can be claimed for the same inoculations without a posterior Schick test". In a long experience of this test, which is a regular feature of the immunization routine in the area where I work, it has been well established that some children under as well as over 5, do not become Schick-negative after a full course—and be it noted both our doses are 0.3 ml. Without a post-Schick test these children, few though they may be, would go undetected, and their parents be misled into a false sense of security. We assume that these Schick-positive children are not immune and we recommend a further inoculation followed by a re-test. The parent almost always acknowledges without demur the logic of this procedure. We use the Schick test as a rough criterion of response, not as an inoculation of antigen, though no doubt the minute amount of toxin introduced does play a part in maintaining immunity—I am etc.

Experiments with Semen

SIR—Mr V B Green Armvater (April 6 p. 546) attributes our inability to confirm his results following the injection of human semen into immature and spayed rodents to the use of semen of low cellular content, stale and decomposed. On the contrary, our semen specimens were obtained less than one hour after assay and immediately placed in a refrigerator. Naturally only samples satisfactory as regards motility and cell content were used. It might be objected that the parenteral method of administration of the semen is not a fair test, and accordingly we recently concluded a new set of experiments using the method of insemination—the results were again negative. It is undoubtedly of great importance biologically and sociologically, that there should be no lingering doubt about the possible function of the semen, and we await with considerable interest the publication of the results of Mr Green Armvater's recent experiments—We are, etc.

Medical Future of the Colonies

SIR—Surely "European M.O." (April 6 p. 551) misses the point completely. The whole question of the disparity in salaries between African and European medical officers is a fundamental one. On what is this disparity based? Is it qualification? Unlikely, since both European and African doctors entering the service usually possess similar qualifications from a university in the British Isles. Is it ability? Definitely not, because as a rule it is the custom of the Colonial Office to appoint all newly recruited doctors as medical officers in the first instance, irrespective of any special training or qualification they may possess. Is it the necessity for supporting two homes?

This is the explanation usually put forward. According to "European M.O." the difference in salary grades is made to compensate the married European officer who has of necessity, to maintain two homes.

If this were the reason for the disparity in salary, then an unmarried European medical officer would be paid at the same rate as his African colleague, because the question of a second home would not arise in his case. Similarly, an African medical officer married to an Englishwoman and who has set up a home in England would be paid the same salary as a married European colleague. But in neither of these cases is such an adjustment in salary made. Then this question of schooling for the married European medical officers' children. This need not cost anything. For there are not free elementary and secondary schools all over England? He may, of course, elect to send his children to the more fashionable public schools, but (if I may quote "European M.O. here") "that would be from choice, no necessity." On the other hand, "European M.O." is wrong in suggesting that it is unnecessary for the African to send his children to Europe to be educated. There is a serious shortage of both elementary and secondary schools in Nigeria to-day, and university education is non-existent. There is a sort of medical school, but it grants a diploma which is not recognized by the G.M.C. or any other body, except itself.

Here, then, are two doctors both possessing identical qualifications, both more or less of the same ability, and both serving in the Colonial Medical Service—say in Nigeria—one is an Englishman and the other an African. The Englishman's salary starts at £600, and ends at £1200. The African gets £400 to start with and ends up by receiving £720. There can therefore be no other possible explanation for this disparity in salary but that of racial discrimination. It is surprising that Africans enter the service at all in view of these conditions. The reason I believe they do this is that the standard of living in the country is so low that private practice, which is the alternative, is not remunerative. Can anything be done to alter the position? That depends on the persons most concerned—namely, the African members of the Colonial Medical Service. If they are dissatisfied with their position they should do something about it. Call for sympathy from "A Colonial" is well meant but ineffective. "European M.O." is not only unsympathetic, but advances the time-worn and puerile argument of the necessity for running two homes and also by some very curious calculation makes out that there is no inequality between the European maximum salary of £1200 a year and the African's maximum of £720.

Nigeria has a population of about 22 millions, and fewer than 400 doctors. Might one suggest to the Colonial Office that instead of being almost completely dependent on recruitment of medical officers from Great Britain, a better way towards providing an adequate medical service for West Africa would be the immediate establishment of a medical school locally. For I am sure many of these European medical officers would much rather work at home, and be with their families instead of going out to West Africa where (so one is told) "the climate is bad, and the salary no better."

A final word. Is the salary offered the European medical officer as meagre as your correspondent would have us believe? It would be interesting to know how much additional income European medical officers in the Colonial Medical Service earn by carrying on private practice—I am, etc.,

H OPISHELOLOMI THOMAS

Quinine for Induction of Labour

SIR—May I, as a very junior obstetrician, be permitted to enter into the stormy controversy which has been aroused by Mr F Neon Reynolds's brief but precise statement on present-day orthodox obstetric thought with regard to the use of quinine for the induction of labour at term.

The letter by Dr E K. Mackenzie (March 2, p. 332) on this subject demonstrates a rather appalling lack of effort in the perusal of modern publications, most of which acknowledge the foetal risks associated with the use of quinine, some conceding that there is a 1% foetal mortality rate directly associated with its use. This matter has, of course, been dealt with in previous correspondence by Mr Wilson Clyde (March 16, p. 407). Dr Mackenzie claims that his results are

very significant as against the unsupported statement of Mr. Reynolds. Obviously Mr. Reynolds hardly thought it necessary to produce statistics to support a relatively well-known fact.

However, the tone of Dr. Mackenzie's letter suggests that he is getting at something else other than the dangers of the use of quinine for the medical induction of labour. His references to higher qualifications, maternity hospitals, and aseptic precautions are reactionary, to say the least, and in his most recent letter (April 6, p. 547) Dr. Mackenzie infers that obstetric teaching could be better done by G.P.s rather than by the recognized masters of the art. I feel sure that it would be quite an eye-opener for Dr. Mackenzie if he were to spend a few weeks in a maternity hospital and see for himself a few of the cases of obstetric malpractice which occur at the hands of the G.P. dabbling in obstetrics.

I am not suggesting that all G.P.s are unsuitable for the practice of obstetrics—far from it—but I am suggesting that they should be up to a certain minimum standard before being allowed to practise obstetrics. After all, good midwifery is a very time-consuming practice, and few G.P.s can spare the time required; hence their greatest failing in this field—namely, meddling midwifery. If, as Dr. Mackenzie suggests, we younger men were to be trained "in the hard school of general practice" rather than under the skilled eye of a master obstetrician, many of the mistakes which are all too commonly made would be perpetuated—surely a retrograde step.—I am, etc.,

Nantwich, Cheshire.

J. KENWORTHY OGDEN.

Unusual Reaction to Penicillin

SIR,—A number of different reactions to penicillin have now been described, but I would like to submit the following account of a case I attended recently as being a most unusual reaction to penicillin.

The patient, aged 24, was admitted on March 28 suffering from gonorrhoea. He gave no history of previous reactions to injections, and had not previously had any penicillin. At midday he was given an injection of 20,000 units of calcium penicillin (intragluteally) with no untoward result. At 3 p.m. he was given a further 20,000 units. At 5.30 p.m. he started to complain of dizziness and a feeling as if he were "blown up like a balloon." There was no local reaction at the site of injection. He appeared as if drunk, with staggering, incoordinated gait and slurred irrational speech. His temperature mounted rapidly, and at 5.45 p.m. was 104° F. (40° C.). He was put to bed (with difficulty) and went into a deep comatose sleep from which it was difficult to rouse him. His temperature at 9 p.m. was 99° F. (37.2° C.).

The following morning he felt much better, but still complained of slight dizziness, and in addition had a severe headache and blurring and dimness of vision. Temperature was normal. The following day the symptoms had vanished completely, and a test dose of 10,000 of penicillin was given. No reaction followed this, and three days later a further 10,000 units was given without any trouble. Thus the full course of treatment was completed without

I should be very interested to learn if any other medical officers have noted a penicillin reaction of this nature.—I am, etc.,

B A O R

MARK SWERDLOW,
Capt., R A M C.

Standardized Nomenclature and Formulae

SIR,—When I first began to learn medicine the *British Pharmacopoeia* contained all our drug requirements. Nowadays we seem to depend to an increasing extent on large manufacturing chemical firms, who produce and advertise synthetic drugs of which the public seem to know nearly as much as we do ourselves. (When you get a black man in the heart of Africa coming and asking for "siki-nine-three" it opens your eyes.) No one will dispute the value of these modern discoveries, but what one does deplore is the fact that every firm turns out identical products under different names. This applies notably to the sulphonamides, the barbiturates, the various endocrine products, while we have atebirin, mepacrine, and quinine as another instance.

Personally I find it impossible to keep pace with so many different names for the same thing—different names merely because they are made by different firms. I was discussing this recently with a well-known pharmacist in Nairobi, and we agreed that the time had come to effect some sort of standard nomenclature, which should be international if possible. Apart from the difficulty of remembering all these varieties by the doctor, it is almost impossible for the retail chemist to maintain stocks of, say, a dozen different presentations of the same drug. It would be very helpful to both the doctor and the retail chemist if it were possible to deal with this state of things by standardizing the nomenclature and the formulae.—I am, etc.,

Nanyuki, Kenya.

G. DUNDERDALE.

Physical Therapy in Mental Disorder

SIR,—As a general practitioner who has at times to send patients to psychiatrists, I am distressed at not reading any explanation of the quotation in Dr. C. G. Learoyd's letter (March 30, p. 505). There is no doubt whatever of the fear of E.C.T. entertained by patients returning to hospital a second time. Apart from the humanitarian point of view, it is not a nice thought that the ratepayers' money is financing practices which are matters of terror and dread to their fellow creatures—and it must not be forgotten that these fellow creatures, because of the very nature of their malady, are the only members of the community who are incapable of voicing their wrongs and grievances.—I am, etc.,

Lamberhurst, Kent.

DORRIT WATERFIELD.

Obituary

J. E. S. FRAZER, D.Sc., F.R.C.S.

Prof. J. E. S. Frazer, who died suddenly on April 15 at Cathcart Road, London, S.W., was appointed head of the anatomy department at St. Mary's Hospital Medical School in 1911. He received the title of university professor in 1915 from the University of London, and that of emeritus professor on his retirement owing to ill-health in 1940.

John Ernest Sullivan Frazer was born in London in 1870 and went from Dulwich College to St. Bartholomew's for his medical training. As a student he won distinction in athletic sports. He qualified in 1891 and then spent seven or eight years in London and provincial hospitals. In 1898 he took the F.R.C.S., but his health being impaired by infection from a wound in the post-mortem room he decided to make his career as an anatomist and was appointed demonstrator in that subject at St. George's Hospital. He transferred to King's College in 1905 and to St. Mary's Hospital six years later. As a teacher his value to the department proved inestimable, and during his period of office at St. Mary's he opened and equipped an anatomical museum which was a boon to generations of students. He was Hunterian professor at the Royal College of Surgeons in 1915–16 and examiner in anatomy for the College and for the Universities of Oxford, Cambridge, Durham and London. During the war of 1914–18 he acted as temporary out-patient surgeon at St. Mary's.

Prof. Frazer's most important contribution to the advancement of knowledge was his textbook *The Anatomy of the Human Skeleton*, which was published in 1914 and reached a fourth edition in 1940. His *Manual of Embryology* ran into a second edition. In 1937 he revised and edited Buchanan's *Manual of Anatomy* and (with Dr. R. H. Robbins) Buchanan's *Manual of Practical Anatomy*. All Frazer's writings proclaim him a keen observer accurately recording what he has seen with the certainty of an eyewitness. His researches in embryology are well known and include eleven papers in the *Journal of Anatomy* (1915–35). He held office as secretary of the Section of Anatomy and Physiology at the Annual Meeting of the B.M.A. in Birmingham in 1911, and had been secretary and president of the Anatomical Society of Great Britain and Ireland.

Dr. ERIK D. SODERSTROM, of the Swedish Evangelical Mission, was a well-known and much-loved figure in Ethiopia, and will be missed by all who knew him; more even by Ethiopians than by his many European friends and acquaintances. His work lay chiefly in Wallega Province; and in Lekempt, the capital, he built his hospital and laboured for many years, the Italian occupation and Ethiopian reoccupation interrupting or seven years, during which time he worked in South Africa. Erik Daniel Soderstrom was born at Ringarum, Sweden, in September, 1890, and studied medicine in Edinburgh from 1910 to 1916, when he qualified M.B., Ch.B. From there he proceeded to the Liverpool School of Tropical Medicine and obtained the D.T.M., and then until he sailed for Ethiopia in 1919 he held house appointments in the Midlands. Once in Ethiopia, he, with his wife, settled down in the then little-known town of Addis Ababa for a full two years, until permission could be obtained for work in the interior. This was granted, and they set off for the west, where, in Lekempt, they did medical missionary work in primitive huts for eight years. Ras Tafari, the then Regent and now Emperor Haile Selassie, gave money for a hospital and this was finished in 1931. From then until the Italian invasion the work progressed well, but the actual appearance of the enemy brought this to a standstill, and the missionaries escaped through the Sudan to take up an appointment with the Church of Sweden at Ceza, their mission station in Zululand. Here Dr. Soderstrom laboured for five years. The return to Addis Ababa in 1943, the few months' work with the British Red Cross Medical Unit, and the departure once again to take up hospital work in Lekempt were painful experiences—though it was no easy matter to pick up the threads under such altered conditions. His welcome back was undoubted—he was a father to them all and was loved by all, high and low alike. He died on Nov. 10 of complications following typhus, probably caught through a visit to the prison during an epidemic he was fighting, which carried off hundreds in the neighbourhood.—G. L. L. G.

Medico-Legal

MEDICAL MAN'S SLANDER ACTION £2,000 Damages against Woman

In the King's Bench Division of the High Court of Justice on April 12 Mr. Justice Charles gave judgment for the plaintiff, awarding him £2,000 damages, in an action for slander brought by Dr. Arthur Henry Hennessy, of Sanderstead, Surrey, against Miss Irene Boyanton, of Sanderstead. The plaintiff's case was that the defendant made false statements about him, in which she alleged that he had made love to her and criminally assaulted her in his surgery on Sept. 26, 1944, and that he had thereby been greatly injured in his character and profession.

This High Court action was a sequel to a disciplinary inquiry held by the General Medical Council on May 31 and June 1 and 2, 1945. Dr. Hennessy had been summoned before the Council on the charge that, being a registered medical practitioner, and standing in professional relationship to a lady described as "Miss A.B.," he on Sept. 26, 1944, attempted to commit adultery with her, indecently assaulted her, and assaulted or was party to an assault upon her. The complainant was "Miss A.B." After a hearing *in camera* which lasted altogether more than eleven hours, the decision of the G.M.C. was announced in public by the President, who said that the Council found that the facts alleged against Dr. Hennessy had been proved to their satisfaction, and that in respect of the facts so proved they judged him to have been guilty of infamous conduct in a professional respect and instructed the Registrar to erase his name from the *Medical Register*.

In the High Courts on April 10, 11, and 12 Mr. Holroyd Pearce, K.C., appeared for Dr. Hennessy, and, dealing with the alleged slander, said that the words were uttered by Miss Boyanton to another doctor in Sanderstead and to a garage proprietor. "The tragic part of this case came later. Miss Boyanton set the General Medical Council in motion in 1945. Deliberate perjury before that body resulted in Dr. Hennessy being struck off." During the course of the hearing Mr. Justice Charles repeatedly referred to the defendant's "lies." He ordered the documents to be impounded to consider whether Miss Boyanton should be prosecuted in the criminal court for perjury. With reference to the action of the G.M.C. in striking

Dr. Hennessy off the *Register* his lordship said: "Not having the mass of evidence which was before me, their inquiry resulted, in my firm and clear conviction, in a gross miscarriage of justice." In the course of his judgment he said that the slanders alleged were very wicked lies if they were not true. His lordship accepted Dr. Hennessy's denials and rejected Miss Boyanton's story of a criminal assault. Giving his reasons for disbelieving her allegations he pointed to the fact that throughout the relevant time one of the plaintiff's patients, with her infant daughter, had been in the waiting room adjoining the surgery, had seen Dr. Hennessy and Miss Boyanton come out and had noticed nothing unusual about them. Referring to certain evidence which had been called in support of Dr. Hennessy's case his lordship found it difficult to believe that if the General Medical Council had had that evidence before them they would not have believed it in preference to that of Miss Boyanton, for she patently lied. He must award the plaintiff substantial damages to exhibit to the world at large that he (his lordship) had not believed one single word of the slanders, and he granted an injunction to restrain the defendant from uttering any similar slanders in future. He hoped in conclusion that the G.M.C. would see their way to reinstate Dr. Hennessy on the *Medical Register*, and he undertook at counsel's request to communicate with the Council.

Universities and Colleges

ROYAL COLLEGE OF SURGEONS OF ENGLAND

A quarterly meeting of the Council was held on April 11, with Sir Alfred Webb-Johnson, President, in the chair.

The Walker Prize of £100 was awarded to Prof. E. C. Dodds, F.R.S., for his work on the synthesis of stilboestrol and dienoestrol, which has proved most valuable in the treatment of prostatic cancer. The John Hunter Medal and Triennial Prize of £50 was awarded to Dr. Joan M. Ross for her outstanding work in pathological anatomy, particularly in regard to the collection of pathological specimens illustrating injuries and diseases occasioned by the war. The Begley Prize for 1946 was awarded to Otto Fleischner of the University of Vienna.

Mr. W. Rowley Bristow was elected Robert Jones Lecturer for 1946.

Dr. G. M. Ververs, superintendent of the Zoological Society, and Mr. A. J. Darden Smith, surgeon to Mount Vernon Hospital, being members of the College of 20 years' standing, were elected to the Fellowship.

Surg. Capt. Lambert Rogers was re-elected a Member of the Court of Examiners.

It was decided to hold special courses in anatomy, applied physiology, and pathology for the Primary Fellowship Examination, September to October, 1946.

The following was set as the subject for Jacksonian Prize Essays for the year 1947: "The Surgery of the Lower Oesophagus and Cardiac End of the Stomach." The following was set as the subject for the Cartwright Prize Essays for the five years ending 1950: "The Healing of Injuries and Post-operative Lesions of the Jaws." Copies of the regulations governing the award of both these prizes may be obtained from the secretary of the College.

Diplomas of Membership were granted to J. Cox, J. R. Hawkins, and Margaret H. Pond.

Mr. Charles Leopold Mayer, of New York, who on previous occasions has given considerable sums for medical research, has awarded a prize of £1,000 to Mr. Terence Millin, F.R.C.S., of All Saints Hospital, London, in recognition of his contributions to the advancement of surgical treatment of the enlargement of the prostate. The prize was presented to Mr. Millin at a meeting of the Council of the Royal College of Surgeons on April 11.

The following lectures will be delivered at the College (Lincoln's Inn Fields, W.C.) at 5 p.m. on each day:

Erasmus Wilson Demonstrations: April 29 and May 1, Mr. L. W. Proger, Some Original Pathological Specimens from the Hunterian Collection; May 2, Mr. T. M. Tyrrell, Inflammation and Repair in the Tissues of the Eye.

Hunterian Lectures: May 9, Prof. D. H. MacLeod, Endometriosis—A Surgical Problem; May 16, Prof. B. W. Rycroft, War Wounds of the Eye and their Treatment; May 23, Prof. J. Chamley, Conservative Treatment of Fractures of the Femoral Shaft; May 30, Prof. C. G. Rob, Diagnosis of Abdominal Trauma in Warfare.

Medical Notes in Parliament

Health Bill Second Reading

The Second Reading of the National Health Service Bill will be taken in the House of Commons on April 30, May 1, and part of May 2.

HOSPITALS AND THE HEALTH SERVICE DEBATE IN HOUSE OF LORDS

In the House of Lords on April 16 Lord MORAN drew attention to the Government White Paper on a National Health Service and moved that the House, while regretting any measures which might impair the efficiency of the general practitioners' service, welcomed proposals for the better co-ordination of the hospital services of the country. He explained that he spoke personally and not for his colleagues. He said three questions had to be answered. Was a drastic re-organization of the hospital system of the country necessary? Surveys made for the Ministry of Health during the war showed that one-third of the 93,000 beds in the 1,059 voluntary hospitals in England and Wales were in voluntary hospitals which had fewer than 100 beds each. Generally these hospitals were much too small. In too many of them major surgery was performed by men without surgical training, and the duties of physicians were usurped by those who had not the training of a physician. In municipal hospitals a more disturbing situation was found. Of 152,000 beds in these hospitals in England and Wales 78,000 were general beds, of which 29,000 were in public assistance institutions, which provided little but food and shelter.

Generally speaking, voluntary hospitals in the future would have greater difficulty in balancing their budgets, and could not begin to meet the capital expenditure required after six years in which nothing had been spent in building or equipment, or was required by the effects of bombing. The hospitals would have to call on the Government for a considerable sum of money. Such public expenditure probably meant some measure of public control. Who was to exercise that control? Every discussion among consultants and specialists who worked in these hospitals had been dominated by the fear that the hospitals would come under the control of local authorities. Because the White Paper appeared to lift that menace from the profession many consultants and specialists were reconciled to the passing of the voluntary system. Doctors dreaded being put under local authorities because the doctor had so little to say and because of the greater delays in getting anything done. Even in the R.A.M.C. during the war, under an able Director-General, the rigidity of a great service interfered with research. During a big outbreak of diphtheria at Alexandria guinea-pigs were necessary to trace the carriers, but had to be obtained as "Red Cross Comforts." It was true that doctors were working happily under the Middlesex and Surrey County Councils, but the present view was such that no statesman would dream of putting doctors and hospitals under local authorities. If hospitals were not to be controlled by these, they must be controlled by the Minister.

THE QUESTION OF OWNERSHIP

So far there was agreement between the great majority of consultants and specialists. But there was great difference of opinion in the profession on whether this control should imply the transfer of the ownership of hospitals. One view among his colleagues was that the Minister should give a block grant to a region. That block grant could be used so that any local hospital which remained backward could be made to come into line. Other sections of the profession held that if such sanctions were applied to a powerful local authority, there would in the end be a local authority majority on the Regional Board—the thing which the profession wished to avoid.

Supposing the change of ownership took place, there would be gained financial peace and the co-ordination of hospitals; and freedom from the menace that the hospitals would be put under the local authorities. The Minister of Health had refused to blunt the edge of medicine as the teaching hospitals were left alone, a thing which the profession asked in vain from Mr. Willink. On the other hand, the profession lost the voluntary system; but since almost every addition to knowledge had come from teaching hospitals and those were left intact the essence of the voluntary system was preserved. Men had chosen to work within these hospitals because they found their intellectual freedom. He himself, as Dean of a Medical School, had seen how the interest of inspectors from the University of London and the University Grants Committee seemed to disappear at the door of the pathological institute

because the personality of Sir Almroth Wright had alienated the official world. If he had been in a service he would have had a thin time. Yet it was from that laboratory that penicillin came. The man of initiative should be given his head, however angular it might be. The voluntary hospital had a personality which stirred up around it a spirit of service. Was it necessary that that should be lost? Sir William Goodenough and the Secretaries of the King's Fund had proposed that within the fabric of the White Paper all voluntary hospitals should have larger autonomy and some control over their finances. He believed Mr. Bevan would go carefully into these suggestions, while not forgetting that the more the local management committee gained in power the less would be the influence of the university.

COMPOSITION OF REGIONAL BOARDS

Acceptance of the principles set out in the White Paper was always qualified by the proviso that "the composition of the regional boards is satisfactory." These regions would be able to say whether a hospital should expand and would be able to take away departments. To the professional world such powers were a matter of life and death, and doctors had repeatedly asked the Minister to reveal the composition of the regional board. Up to date he had refused that information. He (Lord Moran) now asked for it, but said he did not share the suspicion that Mr. Bevan was going to let the local authorities in by the back door and give them control of these regional boards. He believed that Mr. Bevan had learned from the experience of the Nuffield Provincial Hospital Trust, who found that the only way to make such boards work was to handpick the men. He did not think that anyone had been happy on the proposals concerning the endowments of hospitals, but he did not agree that the use of £32,000,000 sterling, not for one hospital but for more than one, merited the word confiscation. It was not reasonable that if the Minister took the liabilities of these hospitals and made himself responsible for their maintenance he should be deprived of their assets.

THE G.P.'S INCENTIVE

It was difficult to say what the general practitioner thought of the proposals in the White Paper, but there was a fairly general disquiet among practitioners for only one reason, and that was the dread that these proposals might lead to a whole-time service. General practitioners were critical of health centres and of the abolition of the sale of practices, because they regarded such things as a first step towards a whole-time service. He himself, after 25 years as Dean of a Medical School, was unable to say what effect a whole-time service would have on the practice of medicine. It was clear that such a service—without an adequate incentive—would be a bad service. It was not only the financial incentive that mattered. It was the conditions under which men worked and whether the work was stimulating. The life of a general practitioner in recent years had lost something of its colour. He had seen the treatment of serious disease pass out of his hands. Presently, there was almost certain to be a sharp division between consultants and general practitioners on the ground that if a man practised a specialty he should be trained for it. That division would take the milder degree of specialization out of the general practitioner's hands and deprive his life of interest. If his life were made duller, this would have an effect on the men who entered the profession. At present, the doctor lived for his work. Would the conditions in the White Paper attract in the future the kind of man who in the past had won the regard of the public? These questions would determine whether Parliament was working wisely for the betterment of the profession and for the good of the country. He himself had no answer to them.

Lord INMAN said he had been engaged in hospital work for 25 years at a London hospital. A number of Poor Law infirmaries had been upgraded, and there were cases where they were acknowledged to be among the best hospitals in the country. In the past, through over-lapping and rivalry, there had been cases where some hospitals had long waiting lists while close-by were hundreds of vacant beds. Changes of a radical character must be made and these changes were introduced in the new measure. He believed its purpose was a nation-wide service which would bring within the reach of everybody the best medical advice and treatment. Because that was the broad conception he would give the measure his support, while reserving the right to comment on some of the proposals. He hoped that in the transfer of institutions to regional boards care would be taken to preserve the enthusiasm and the readiness to serve which the local institution attracted to itself. He saw no reason why voluntary support should not continue, and, in fact, the measure made provision for its continuance in unpaid membership of governing bodies, regional boards, and management committees.

THE MEDICAL SUPERINTENDENT

Lord DONOUGHMORE pointed out that in the voluntary system a board elected by supporters of the hospital worked in harmony with the medical committee, meeting at the hospital, but in the municipal system the governing body was a committee of the council meeting at the county hall. The latter worked through the medical officer of health and through a medical superintendent. He did not believe such a superintendent was a wise substitute for a medical committee representing all the medical departments. He was a little frightened at an advertisement in which the Ministry of Health invited applications for posts as 'Nursing Officers'. These individuals were to inspect nursing and staff establishments in general, and especially at hospitals and other places for the training of nurses. He asked whether they were to work under the regional bodies or whether they were to be representatives of the Ministry of Health working independently of the regional bodies. He further asked whether the regional authorities were going to be interfered with from headquarters. If that was to be the case, the scheme would fail. He wanted to know in what spirit this new system was going to be worked.

Lord GEDDES was certain that on the composition of the regional hospital boards the well being of the general hospital service would turn. Given proper boards and adequate finance, the co-ordination would be obtained which would bring hospital services up to a proper standard. He thought that the polyclinics, which the White Paper called health centres, would not make for confidence between patient and doctor. A secretarial service would be provided at each centre, and medical records would be kept by the servants of local authorities, men and women would be unwilling to attend because records of their maladies would pass through the hands of some not very responsible girl or man clerk. Was it not possible instead of health centres to provide diagnostic centres where experts would do x-ray work, laboratory investigations, etc., for general practitioners? It was possible to improve Mr. Bevan's proposals, which in many parts contained an extraordinary number of good points though some would not make for the relations which should exist between patient and doctor.

Lord PIERCY said the general practitioner would rather be able to use aids to diagnosis under his own control at a health centre than go to a diagnostic centre such as was suggested by Lord Geddes. Under the new conditions the life of the ordinary doctor would be more interesting and stimulating than it commonly was now.

Lord LUKE said much had been heard about the taking over from the hospitals of endowments valued at £32,000,000, but not so much about the buildings, equipment, and land which were also being taken. The total value of what was being taken over from the voluntary hospitals was more in the region of £250,000,000 than £32,000,000. The voluntary hospitals had to exist for another two years as they were, because the legislation would not come into effect until 1948. He hoped that this would be made plain to donors of voluntary gifts.

VIEWS OF THE ROYAL COLLEGES

Lord HORDER thought that the motion of Lord Moran was premature. He was glad that Lord Moran made it clear that he was speaking for himself. In the previous week the Royal College of Surgeons and the Royal College of Obstetricians dissociated themselves definitely from approval of the transfer of ownership of the voluntary hospitals. Yesterday this matter came under discussion in the College of Physicians, but Lord Moran, in his speech to the House, had made no reference to the opinions of this College, over which he presided. Against this negative view of the Royal Colleges, King Edward's Hospital Fund had asserted that the success of the Bill would largely depend on spreading local interest over all the units composing the new service. It said that amendments were essential to provide for a measure of independence for the hospital management committees. The British Hospitals Association stated in the previous week that the provisions of the Bill relating to hospitals were not in the best interest of the patient and the community.

Lord WALERAN asked whether the Ministry of Health would expect the Voluntary Ambulance Service to serve the hospitals under the terms of the White Paper or would expect the St. John Ambulance Brigade to maintain its ambulances from voluntary contributions.

GOVERNMENT REPLY

Replying to the debate Lord LISTOWEL said the proper occasion for the Government to submit the case for a comprehensive health service was during the Second Reading of the National Health Service Bill in the House of Commons, and subsequently in the House of Lords. It would be an advantage to

the Lords to discuss this subject again later in the session. He expressed his regret that Lord Dawson of Penn and Lord Moyihan had not been spared to offer their advice at this turning point in British medicine. The regional hospital boards were to administer all the hospitals with the exception of teaching hospitals, and it would be a mistake for the Government to lay down in advance their exact constitution. Their size and composition must vary according to the needs of the area and to the services they would be expected to provide. The boards would consist of people chosen for their individual suitability as experts and not as delegates or representatives of different interests in the area. The only rigidity in the composition of new boards would be the inclusion on each board of at least two experts on mental health. It was unlikely that on any board so constituted the local authority members or any other distinctive group would obtain a clear majority, he could safely give this assurance to Lord Moran.

The object of the Government's proposals for future administration of the hospitals was the maximum devolution and local independence obtainable within the regional framework. Decentralization was the goal. There would be a wide field of financial autonomy. Management committees would have unfettered financial freedom within the limits of their annual budget, and no Treasury interference. Regional boards would also have moneys available from the Hospitals Endowment Fund, and any gifts from future donors, to spend at their discretion. The day to day running of the hospitals by the management committees would not be hampered in any way by the regional authorities.

It was a complete misunderstanding to suggest that the proposed health service would deprive the medical profession of much independence by turning its members into employees of local authorities. Even in health centres, general practitioners and dentists carrying on their practice in groups from the centres would not be employed by the local health authorities. The proposed Medical Practices Committee would have no powers for directing a general practitioner into a particular practice, but the need for a body to distribute doctors evenly throughout the country was essential to any health service which set out to cover the needs of the whole population, this had been recognized in the White Paper published in 1944 by the Coalition Government. Under no circumstances would the Medical Practices Committee be able to tell an applicant that he must go to a particular area. The committee had power to refuse a doctor admittance as a practitioner to certain parts of the country, but this procedure could not be described as direction. The Medical Practices Committee would perform the functions of an Appointments Board or Employment Agency.

THE SLOGANS AND HEALTH CENTRES

Lord MORAN agreed that if the regional board was trusted and was a really good board the whole scheme would work. If, on the other hand, there was interference it would not work at all. He said he was an unrepentant advocate of health centres. The reason why the motion had been brought forward was that meetings all over the country were having put before them not the considered views of people who had followed the subject on negotiating committees, but in many cases just slogans, and great harm was being done. It was imperative that somebody should try to rescue this question from slogans. Lord Horder had mentioned the Royal College of Physicians. Consequently, Lord Moran read the motion passed by that College, which was:

"That the College approves the central direction and co-ordination of the general policy of hospitals provided the composition of Regional Boards is satisfactory."

That was an innocuous motion. He thought it would be perfectly frank to say to the House, however, that there was a great difference of opinion on this subject, and he thought he made it clear that he was speaking as an individual.

The motion was, by leave, withdrawn.

Voluntary Hospitals' Income

On April 8 Mr. BURNS asked what percentage of the expenditure of voluntary hospitals was provided from private sources or from public funds. Mr. KEY answered that the latest published figures available for England and Wales showed that in 1941, 36% of the hospitals' income was derived from voluntary sources, of which more than half came from income on investments and legacies; 24% was derived from public funds, and the remaining 40% from payments by patients, including payments through contributory schemes.

Compulsory Pasteurization of Milk

On April 10 Lord ROTHSCHILD called the attention of the Government to the urgent need for compulsory pasteurization of milk in as many parts of the United Kingdom as was prac-

ticable, and moved for papers. He said that if the annual number of deaths through drinking raw milk contaminated with bovine tuberculosis were put at 1,600, the number of casualties would be between 7,000 and 8,000. These casualties, which required months of hospital treatment, were a source of misery and anxiety to their families and grave expense to the State.

One objection raised to pasteurization was that it took "the life out of milk." Minor changes were brought about in the composition of the milk, but investigations in animals showed conclusively that such changes had no appreciable effect on its nutritive value. According to the National Institute for Research in Dairying the difference in composition between raw and heat-treated milk had been found to be less than that between samples of raw milk from different herds. The opponents of pasteurization also said that it destroyed the need for the T.T. and attested-herd schemes, but these schemes were directed towards improving the health of our cattle as well as towards producing germ-free milk. The heat treatment of milk was directed primarily towards improving the health of the population and reducing the unnecessary deaths each year. To the objections that heat treatment would put small producer-retailers out of business and reduce the nation's milk supply, he replied that the compulsory institution of heat treatment in towns with a population of more than 20,000 would have no effect on small producer-retailers; and far from reducing the nation's milk supply, might well cause an increase.

Earl De La WARR said it was better to produce clean milk than to kill the germs in dirty milk. But there was no doubt that the majority of medical and scientific opinion was in favour of pasteurization, at any rate of our large urban supplies of milk that had to be bulked. The Government and the Milk Marketing Board should, therefore, start with compulsory pasteurization in areas of 20,000 population or over, and then steadily extend it elsewhere to those producers and distributors who were not prepared or able to offer to the public milk of a designated standard. A reasonable period should be allowed for reaching that standard, but there should be a definite time limit. They should have to reach accredited standard in two years, something considerably above that in five years, and full T.T. and attested herd standard in 10 years. They should also make sure that the designated milk was kept separate from the rest. In the meantime we should intensify the campaign for cleaning up herds and rearing a good supply of healthy stock. Viscount BLEDISLOE emphasized the necessity for improving animal health; pasteurization was not an alternative to animal health but was complementary to it.

Lord AMMON, replying for the Government, said that their plans for better quality milk had been set out in a White Paper issued in 1943, which was strengthened by a Defence Regulation requiring a supply of clean milk in certain areas. There were 621 "rationalized" milk areas in England and Wales, and schemes to make the White Paper proposals effective, which the Government invited from dairymen, had so far been received from one-third. Shortage of plant had been a difficulty, but that was being gradually overcome and small quantities of plant were being imported. It was regrettable that more schemes had not been submitted, but a more active policy would be pursued when opportunity, labour, and plant made that possible. To encourage the heat treatment of the maximum quantity of milk the Minister of Food had, since April 1, 1944, paid 1d. a gallon to milk distributors on all milk subject to that treatment. That was to be increased to 1½d. a gallon from April 1, 1946.

Of the total annual liquid milk consumption of 1,075,000,000 gallons approximately 725,000,000 gallons were heat treated. Of the remaining 350,000,000 gallons not heat treated about 190,000,000 gallons were sold by producer-retailers, and of that about 18,000,000 gallons were from T.T. herds. An efficient system of heat treatment destroyed the germs in milk, and the Health Departments were satisfied that the food value of the milk was not thereby prejudiced. Experiments had proved that the heat treatment caused changes in milk, but they had no significant effect on its value as a food.

The motion was, by leave, withdrawn.

Health Service Bill

Replying on April 11 to Mr. Churchill Mr. HERBERT MORRISON said the Government had decided to meet the request that the second reading of the National Health Service Bill should be postponed till after Easter but felt it could only do so if the Committee and remaining stages of the Bill were not thereby prejudiced. The Government intended to complete the remaining stages in the House of Commons by the end of July. It was now understood that this would not be prejudiced by delaying the second reading.

Mr. Churchill thanked Mr. Morrison for the announcement. He said that in the Bill there were great differences of opinion,

but there was also a much larger common ground of agreement on measures which were contemplated, and even advanced a considerable distance, during the life of the Coalition Government. He trusted that this business would not suffer by the postponement till after Easter.

Mr. Morrison said he recognized that there had been material changes in policy under the present Government and that it was fair that there should be discussion.

Commander GURNEY BRAITHWAITE asked whether it was intended to take the Committee stage of the Bill on the floor of the House in view of the many representations from Members on the subject. Mr. Morrison said that was a point which was usually dealt with when the House reached the second reading of a Bill.

Medical News

A general meeting of the Medical Society for the Study of Venereal Diseases will be held at 11, Chandos Street, W., to-day (Saturday, April 27), at 2.30 p.m., when a joint paper on "Neurosyphilis" will be read by Dr. W. D. Nicol and Dr. M. Whelen.

A general meeting of the Paddington Medical Society will be held at St. Mary's Hospital, Paddington, W., on Tuesday, April 30, at 8.45 p.m., when Dr. D. E. Bunbury will speak on "Recent Developments in Psychological Medicine." A discussion will follow.

A meeting of the London Association of the Medical Women's Federation will be held in the Common Room of B.M.A. House on Friday, May 3, at 8.30 p.m., when Dr. V. Mary Crosse will speak on the care of the premature baby. Coffee 8.15 p.m.

The British Homoeopathic Association has arranged a conference on "Homoeopathy and the State Medical Service" to be held at the Bonnington Hotel, Southampton Row, W.C., on Saturday, May 4, at 11 a.m. A special meeting of members of the association will be held at 2.15 p.m.

A meeting of the Medical Society of the L.C.C. Service will be held at the County Hall, Westminster Bridge, S.E., on Wednesday, May 8, at 2.30 p.m., when "The Treatment of Minor Injuries and Infections of the Hand," with special reference to bad results, will be discussed. The discussion will be opened by Mr. R. V. Lewis-Lloyd on "Fractures"; Mr. J. Gabe on "Treatment of Injuries to Tendons; Ganglions, etc."; and Mr. J. C. Gillies, on "Infections of the Hand."

A meeting of the Association of Industrial Medical Officers will be held at Manchester on May 16, 17, and 18. Private business will begin at 5.30 p.m. at the Midland Hotel, and will be followed up by a dinner at the Grand Hotel. The remaining days will be devoted to papers and study of the cotton industry. Early application for accommodation and tickets is desirable. The honorary secretary of the association is Dr. P. Pringle (Standard Telephones and Cables, Ltd., Oakleigh Road, New Southgate, London, N.11).

At a crowded meeting of the Chelsea Clinical Society on April 9 Dr. Charles Hill spoke on the subject of "Medicine and the State." He gave a very clear and forceful exposition of the problems to be decided by the profession in relation to the National Health Service Bill. Lord Horder, Rear-Admiral Sir Cecil Wakeley, and many other distinguished members and guests contributed to the discussion.

A meeting of representatives of the voluntary hospitals of London was held at St. Bartholomew's Hospital on April 15. Sir George Aylwen, chairman of the Voluntary Hospitals Committee for London, took the chair. The following resolution was passed unanimously: "That the voluntary hospitals of London, while welcoming a National Health Service designed to co-ordinate the hospital services of the country, urge the Minister to incorporate such amendments in the Bill as at present drafted as will ensure the retention by the voluntary hospitals of their property and management, their entities and their traditions, since only thus in their view can the best interests of the community be served."

H.E. Dr. Ali Tewfik Shousha Pasha, Under-Secretary to the Egyptian Ministry of Health and a delegate at the recent United Nations Health Conference in Paris, has been visiting this country for 10 days under the auspices of the British Council, to study our health services. His programme included interviews with the Minister of Health, Sir Wilson Jameson, Chief Medical Officer, Dame Katherine Watt, Chief Matron (Nursing), and other officials of the Ministry. He has also visited the London School of Hygiene and Tropical Medicine, Southwark Maternity and Child Welfare Centre, and Papworth Village Settlement for tuberculous patients.

Sir Drummond Shiels, M.B., has been appointed Public Relations Officer to the Post Office. He was Under-Secretary for India, and later Under-Secretary for the Colonies, in the Labour Government of 1929-31.

No. 14

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended April 6.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1945 (Corresponding Week)

Rate per 1,000 total births (including stillborn)			34				30			

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales infectious diseases were slightly less prevalent during the week. The largest decreases were acute pneumonia 112, and dysentery 62, while the largest rise was cerebrospinal fever 22.

Scarlet fever notifications showed little change, and the total for the country was 1 less than in the preceding week. The chief local changes in the incidence of diphtheria were a rise in Warwickshire 11, and a fall in Northumberland 10. The largest local variations in the returns for whooping-cough were decreases in London 40, and Leicestershire 36, and an increase in Warwickshire 66.

Measles increased in prevalence in London and adjacent counties, the rises being London 61, Middlesex 54, and Kent 41. Large decreases were recorded in Lancashire 102, and Suffolk 93. The result of these opposing trends was a decline of 14 for the whole country.

Dysentery notifications increased in Surrey from 20 to 67. Other large returns were Lancashire 62, London 28, Middlesex 20, Essex 15, Leicestershire 13, Warwickshire 12, Gloucestershire 10.

In Scotland there were 131 more cases of measles and 22 fewer cases of dysentery. The total of 34 cases of dysentery is the smallest weekly total of recent months, and Glasgow with 14 cases was the only important centre of infection.

In Eire there was an increase in scarlet fever 11, enteritis and diarrhoea 10, and whooping-cough 7. Notifications of diphtheria fell by 5, and the 46 cases recorded involved 28 registration areas.

In Northern Ireland the incidence of scarlet fever rose by 11 cases, while there were 5 fewer cases of diphtheria.

Quarterly Returns for England and Wales

The birth rate during the December quarter of 1945 was 15.3 per 1,000, and was 1.4 below the rate for the fourth quarter of 1944 but 1.2 above the average of the December quarters 1939-43. Infant mortality was 46 per 1,000 live births and was 6 below the average of the 10 preceding fourth quarters. The general death rate was 11.3 per 1,000, being 0.3 below the rate for the fourth quarter of 1944 and 0.7 below the average of 1939-43.

In this quarter 201,760 persons were married, which is 51,880 more than in the December quarter of 1944 and 1,480 more than the average for the fourth quarters for 1939-43.

The provisional rates for 1945 give a birth rate of 16.1 per 1,000. This is 1.4 below the high level of 1944, and 0.1 below the rate for 1943. Infant mortality was 46 per 1,000 live births, and was 1 per 1,000 above the low record of 1944. The general death rate at 11.4 per 1,000 was 0.2 below that of 1944 and was the same as that for 1930, which was the lowest ever recorded. The marriage rate was 18.6 and was 4.3 above that of 1944. The natural increase—excess of births over deaths—was 197,628, the value for 1944 being 252,667 and the average of 1939-43 being 110,538.

Infectious Diseases during the First Quarter

The notifications of infectious diseases in England and Wales for the first quarter are here compared with those of preceding years.

	1940	1941	1942	1943	1944	1945	1946
Scarlet fever	13,399	16,099	14,935	26,759	26,962	19,163	16,952
Whooping-cough	7,441	44,160	18,325	23,005	26,141	19,780	20,053
Diphtheria	9,199	14,533	11,658	10,799	9,004	6,061	6,220
Measles	51,377	204,158	26,538	220,556	20,278	247,438	17,652
Cerebrospinal fever	5,093	4,332	2,412	1,287	978	964	966
Acute pneumonia	23,315	20,190	15,769	18,211	14,977	14,783	16,275
Dysentery	531	1,757	1,674	1,319	2,834	4,631	4,444
Paratyphoid and typhoid	194	235	235	175	111	149	136
Deaths from influenza in the large towns	4,568	2,217	863	1,142	1,131	692	2,156

The increase in diphtheria was expected from the trend of this disease during the latter part of 1945. It appears that its mortality is also rising, for the case fatality in the large towns was 29.5 per 1,000 in the first quarter of 1945, while this year it was 31.4. Cerebrospinal fever has apparently reached a stable endemic level at 2 to 3 times the pre-war figure. Dysentery showed no improvement on the high wartime level. Although the outbreak of influenza was not very large, it was one of the worst in recent years.

Week Ending April 13

The notifications of infectious diseases in England and Wales during the week, included: scarlet fever 1,366, whooping-cough 1,934, diphtheria 463, measles, 2,552, acute pneumonia 871, cerebrospinal fever 78, dysentery 270, paratyphoid fever 4, typhoid 3, smallpox 3 (including 2 imported cases). Deaths from influenza in the large towns numbered 24.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Anthology Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London*.

ANY QUESTIONS?

Sodium Chloride

Q.—*What injurious effects follow the excessive ingestion of sodium chloride, and in what diseases is it contraindicated?*

A.—If salt is given in excessive amounts by mouth the irritation may lead to severe gastro-enteritis, which may be fatal. The systemic effects of excessive absorption of salt are essentially due to the rise in the salt concentration in the body fluids and the dehydration which results from the body's efforts to correct this. In severe cases there may be restlessness, thirst, frequent micturition, dyspnoea, rapid pulse, fever, and coma.

Excess of salt is contraindicated in all conditions in which there is a tendency to oedema, more particularly in the hydraemic type of nephritis and in cardiac muscle failure. It is wise also to restrict salt in hypertension, arteriosclerosis, and obesity. Salt is usually restricted in Ménière's syndrome, and in the dehydrating diets which have been used in the treatment of rheumatism and tuberculosis.

Pregnancy and Cancer of the Breast

Q.—*A nulliparous woman aged 37 had radical mastectomy for carcinoma of the breast a week ago. I now discover that she is two months pregnant. Should the pregnancy be allowed to continue? Will deep x-ray therapy affect it.*

A.—Since pregnancy and lactation favour a rapid growth of carcinoma of the breast, many believe that pregnancy prejudices the outlook in women who are suffering from, or who have recently been treated for, malignant disease of the breast. There is some difference of opinion as to whether interference with the pregnancy is justifiable in such circumstances, but the writer would advise termination in the case in question. If the pregnancy is allowed to continue x-ray therapy is not contraindicated providing the foetus itself is adequately shielded.

Preventing Orchitis in Mumps

Q.—*I have read that orchitis, the common complication of mumps, may have the effect of producing "... a greatly diminished fertility or even complete sterility." Can any prophylactic measures be taken at the onset of the mumps to prevent orchitis?*

A.—There is no measure which, taken at the onset of mumps, will prevent the occurrence of orchitis. Not infrequently, indeed, orchitis actually precedes the parotid swelling. Even strict enforcement of bed rest during the early stage of the illness does not ensure freedom from this complication. It has been suggested, however, that a hydrocele may form early and that it is the tension of the hydrocele plus the orchitis which encourage atrophy. In certain cases, therefore, tapping of an obvious hydrocele might minimize the risk of subsequent atrophy; such a method of treatment is worth trying in suitable cases. Fortunately, the condition is not always bilateral.

Senile Degeneration

Q.—*What are the early anatomical changes in the brain in senile deterioration, and what are the first clinical signs?*

A.—The first anatomical change to be seen in the brain in early senile degeneration is an increased argentophilia of the tissues generally—i.e., they begin to take up silver stains more

readily. This proceeds to the formation of senile plaques, which are accumulations of residues of faulty metabolism in the intercellular substance in the upper layers of the cortex. At the same time there is a thickening and increased argentophilia of the intracellular neurofibrils, and the accumulation of lipoids in the nerve cells. All these changes may be found in apparently healthy though elderly patients and may be accompanied by no obvious clinical signs.

Clinically, the first symptoms are likely to be an increase in moodiness, slight irritability, and a slight though progressive deterioration of memory and intellectual powers. Originality and freshness of imagination are likely to go first, accompanied by an increasing incapacity to deal with what is novel. Failure of memory is shown first in impairment of recollection of recent events, more remote happenings being better remembered.

Teething Pains

Q.—*Teething in children is often painful. Is there any preparation—e.g., a local anaesthetic ointment—which, when rubbed into the gums, affords relief?*

A.—Some relief can be obtained by the use of menthol. A mixture of 1 gr. (65 mg.) of menthol to the ounce (28 ml.) of liquid paraffin is convenient. The mother moistens her little finger in this and gently rubs it over the affected gums.

Impotence after Head Injury

Q.—*Four years ago a healthy male aged 48 had a fracture of the skull, arm, and leg.. He made a full recovery, but was off work for eighteen months. Until the accident he led a normally active sex life, but now he complains of complete loss of performance, though desire remains normal. There was no local injury to the sex organs. What treatment is advised?*

A.—Impotence is not uncommon after a severe head injury without any local injury to the pelvic nerves or the genitalia. The condition is often associated with symptoms of a psychological nature, which are the direct result of the head injury. The patient usually is anxious, shows mood change in the direction of depression, has a poor memory, and has great difficulty in concentrating. The post-traumatic state is also associated with headaches and disturbances in vasomotor regulation. The patient should be explored upon these lines before a decision upon the cause of impotence can be given.

Calcium Balance in Chorea

Q.—*It has been stated that there is a deficiency of body calcium or a negative calcium balance during chorea. Is this so?*

A.—The idea that calcium deficiency is involved in the genesis of chorea appears to have existed for quite a long time. Mutch (1934) quoted Isambard Owen as reporting in the latter half of the last century that the topographical distribution of chorea seemed to follow that of rickets. Warner (1930) suggested a parallel between rickets in infants and chorea in older children. That, however, did not, in the views of either writer, preclude a "rheumatic infection" as the primary cause. Chorea was accepted "as a special type of rheumatic infection" (Campbell and Warner, 1930). The factual evidence is meagre. Carter-Braine, Spurrell, and Warner (1929) demonstrated increased electrical excitability of the neuromuscular junction in chorea, and Warner (1930) reported low serum and cerebrospinal fluid calcium in a series of cases, the values returning to normal on recovery. On the basis of these observations Mutch (1934) treated a series of 19 cases with calcium aspirin (Coplans) in doses up to 45 gr. (3 g.) daily, so combining calcium with the conventional antipyretic treatment. He claimed rapid recovery, with an average of 17 days' treatment compared with the usual 35 days for mild and 67 days for severe cases. The cause of the "calcium deficiency" according to Warner was still under investigation, but nothing further appears to have been published.

On the other hand, Widenbauer (1935) reported (this appears to have been an incidental finding) that four cases of chorea showed marked improvement shortly after being given a yeast preparation, and suggested a deficiency of B vitamins as concerned in the aetiology. Then in 1941 Schwartzman, Dragutsky, and Rook reported that, in view of the satisfactory results with vitamin B₁₂—pyridoxine—in the treatment of nervous irritability

and Parkinson's disease, they tried it on three hospital cases of chorea. Early subjective improvement and rapid recovery were claimed, the duration of treatment being 18, 13, and 28 days in the three cases.

That is the position at present. Two different deficiencies are suggested. Similar effects, in small numbers of cases are reported following treatment with calcium aspartate and with pyridoxine hydrochloride. Further observations are obviously required. The amount of calcium given—up to 45 gr (3 g) daily—was roughly equivalent to that in half a pint of milk. Milk would, of course, provide pyridoxine also. The correlation of chorea with poverty is accepted and poverty, at least before the war, implied poor diet, low in calcium and other essentials. Children, and especially the poorer children, have been drinking more milk during the war years. It would be interesting to know whether the incidence of chorea has fallen.

Alopecia Areata affecting Eyelashes

Q.—After measles a girl of 8 had blepharitis and conjunctivitis which cleared up completely. A few months later the eyelashes in the inner halves of the upper eyelids fell out. This happens repeatedly though there is no sign of inflammation of the lids or conjunctiva. Observation shows that the child cannot pull the lashes out and does not finger the eyelids at all. What is the diagnosis?

A.—The condition may represent a rare form of alopecia areata where the eyelashes come into the circle and are thus shed in an irregular manner. If this diagnosis fits the case then the condition will improve spontaneously, although patches of true alopecia may develop on the scalp. From the small amount of information available it is impossible to go further into the question of diagnosis and treatment.

Balanitis

Q.—A patient has persistent balanitis and attacks of herpes on and under the prepuce recurring every three months. The prepuce is long but retracts readily. What is the best line of treatment? Would penicillin locally help? Can there be a vitamin deficiency? Would circumcision be a cure, and can it be carried out under local analgesia?

A.—Balanitis is usually due to infection with *Treponema balanitis*, sometimes fusiform bacilli are present as well. Accumulation of smegma and moisture tend to retard recovery. In the majority of cases ordinary personal hygiene and keeping the affected area dry are all that is necessary. Various remedies may be tried if this fails—for example, soaking in hydrogen peroxide followed by careful drying and then the application of flowers of sulphur or any mild dusting powder. Sulphanilamide powder may be used if there is evidence of bacterial infection, but should on no account be persisted in for more than five to seven days, lest the patient become sensitized. Penicillin cream (500 units per ml) might be even more effective and is safer if available. If all these measures fail, or in any event if a radical cure is desired, circumcision should be carried out, this can be done with a local analgesic.

There is no evidence that balanitis is due to vitamin deficiency. Herpes is caused by a virus infection and is apt to recur.

Right Iliac Fossa Pain in Pregnancy

Q.—A patient aged 28 now four months pregnant, has severe pain in the right iliac fossa. It radiates into her perineum and right leg, and is brought on by any exertion—walking, defaecation, etc. She had a Gilliam suspension and appendectomy after her first pregnancy. The pain was first noticed during labour and after the delivery of her second child, and was worse during her third labour. There are varicose veins in the right leg. Vaginal examination reveals only tenderness in the right iliac fossa. What are the diagnosis and the treatment?

A.—The cause of pain in the right iliac fossa both in and out of pregnancy is often difficult enough to determine clinically

and it is questionable whether a diagnosis by correspondence will be of much value. Dragging on the round ligaments after Gilliam's operation does sometimes cause pain, and although this is likely to be worse during pregnancy it may also be experienced apart from pregnancy. The history is certainly rather suggestive of this diagnosis. Other possibilities which should be kept in mind are post-operative adhesions, a lesion of the right urinary tract, caecal distension associated with colonic spasm, and disease of the pelvic bones and joints, including sacro-iliac strain. Intravenous pyelography and x-ray examination of the bony pelvis might be worth while. It is tempting to inquire whether the pain was present before the operation and whether it constituted the indication for the appendectomy and correction of the retroversion. If the conclusion is that the pain is due to pulling on the round ligament, a corset firmly applied should give some relief during pregnancy, and there is no reason to fear that natural delivery will make matters worse.

Inhalations for Asthma

Q.—Do you consider that the drugs used in inhalers sold for the treatment of attacks of asthma are harmful in any way?

A.—There is nothing inherently undesirable in treating asthma by inhalations. In fact, there is an advantage in taking the attack early, before it becomes resistant to treatment, and in lay hands inhalation is easier than injection. There are, however, at least three precautions to observe. The first is that due care is taken with habit-forming drugs, such as cocaine. It is said that there is no risk of habit formation if a 1% solution of cocaine is used, and this is an excellent astringent. The second precaution is to avoid irritants, such as high concentrations of creosote. All that is needed is ephedrine or adrenaline and an excipient. A good prescription is ephedrine 1% and cocaine 1% in 4% glucose saline. There are on the market blunderbuss preparations containing papaverine, hyoscine, atropine, adrenaline, pituitary extracts, etc.

The third precaution concerns the use of adrenaline. The usual technique of inhalation is to use a hand atomizer and to inhale for three to five minutes. This is all right with strengths of adrenaline not greater than 1 in 1000. Recently, strong solutions of adrenaline have been employed—1 in 100 or even more concentrated—and with these the technique is quite different—only three or four puffs of the vapour should be inhaled. Patients inhaling concentrated solutions of adrenaline must be warned against exceeding this dosage. There is a real risk of adrenaline poisoning leading to anxiety, tremor, tachycardia, rise of blood pressure, and acute oedema of the lungs.

Urgency Procedure for Mental Cases

Q.—In pre-war days the normal method of certification of people of unsound mind was that of two reports from different medical practitioners and an order from a magistrate. In cases of urgency the Urgency Order was used. I am told by the superintendent of the local mental hospital that the Urgency Order should be used as a routine. I have a patient whose case can not be called urgent. She will not go in as a voluntary patient but she is too difficult to remain at home. I filled up the first of two certificates but the second medical practitioner was unable to complete his because at the time of his examination there were not sufficient grounds. Now I am being pressed to have her removed on an Urgency Order. What is the normal method of removal? In this case what would my legal position be if I were to have the patient removed under an Urgency Order when there are no grounds of immediate urgency, if legal action were taken against me?

A.—The law concerning the admission of persons of unsound mind to institutions has not changed and must be adhered to. To use the Urgency Procedure where the patient's condition does not justify it might lay the certifying practitioner (and the superintendent of the mental hospital) open to an action for wrongful certification. The correct procedure is by petition of the nearest relative, supported by a statement of particulars, two medical certificates, and a reception order signed by a judicial authority. A person of unsound mind who is not under proper care and control may be placed under care by a summary reception order made by a justice of the peace and supported by a statement of particulars and one medical certificate. A private patient (it is assumed that the patient in

this case is not rate-aided) not living with relatives or friends may be placed under care by summary reception order made by a judicial authority on the application of the constable, relieving officer, or officer of the parish.

This does not apply to a rate-aided patient. A rate-aided person of unsound mind is placed under care by a summary reception order made by a justice of the peace. This needs a statement of particulars and one medical certificate. The same procedure may be applied to a person of unsound mind, whether rate-aided or not, who is wandering at large, or to a person who is neither rate-aided nor wandering at large but is of unsound mind and either not under proper care and control or cruelly treated or neglected. A relieving officer or constable may place a rate-aided person of unsound mind or one wandering at large in the observation ward of an infirmary; he is there visited by a justice, who may issue an order detaining him there for fourteen days. In all rate-aided cases the application for a summary reception order is made to a justice of the peace by the constable, relieving officer, or overseer of the parish in which the patient is found.

The practitioner is recommended to read the 1890 Act, or the summary of procedure which will be found in the standard textbooks of forensic medicine.

INCOME TAX

Colonial Medical Service

H. W. asks as to the position if he buys a house in this country for the use of his wife and of himself when he is on leave.

* He will become a British resident, and will be liable to British income tax on the income which he remits to or draws in the United Kingdom. The usual personal allowance would be claimable. The position would be the same if the house were the property of the wife.

Loss on Sale of Practice

D. O. C. A. has sold his practice for £1,000 less than he paid for it some years ago. Can he claim an allowance for the loss?

* No. The transfer of a practice is a capital transaction, and any gain or loss arising out of it cannot be taken into account in calculating income.

Assistant: Employment of Wife

J. M. is an assistant in general practice. His house is provided for him by his principal and some consultations will be done there. He asks, Can I claim allowance for my wife (say, £80 a year) for answering the telephone, etc., or expenses of maid for the same purpose?

* J. M. is assessable under Schedule E and any expenses allowable must therefore be incurred "wholly, exclusively, and necessarily in the performance of the duties of the employment." We very much doubt whether he could maintain that proposition on appeal. If he can, then a reasonable amount—having regard to the time required—could be charged as an expense, whether paid to the maid or to the wife.

Resumption of Practice after Service

"Inquisitive" was released from the Army in June, 1945, and resumed his (specialist) practice in July, 1945. On what earnings is taxable (a) for 1945-6 and (b) for 1946-7?

* (a) On the earnings of that year—i.e., his Service pay (on the basis of a proportion of the previous year's pay) and his actual civil earnings to April 5, 1946. (b) On the amount of his professional profits for the year to July, 1946. Depreciation of the car can be claimed (a) on a proportion of £126 at 20% = £25; assuming that civil work started on or about July 5, 1945, the allowance would be 9/12ths of £25—i.e., £19, plus 1/5th—i.e., £23; (b) on £126 - £19 = £107 at 20%, plus 1/5th—i.e., £28.

Employee: Board and Lodging of Family

S. H. is contemplating employment at an institution. What would be the position as regards income tax if his service agreement provided for payment of a salary of £v plus free board and lodging for himself, his wife, and his six children.

* The matter is not free from doubt. In the old leading case on this question the employee was required to reside on the premises in the interests of his employer, whereas in this case it is the interests of the employee which would be served by having the family residing at the institution. The cost of their board and lodging is the primary responsibility of S. H., and if the managing committee bear that cost for him it might be held that it was equivalent for income-tax purposes to a payment made on his account. S. H. is advised to obtain, if possible, the opinion of the local tax office before entering into such an agreement with the institution.

LETTERS, NOTES, ETC.

Vitamin E in Neuromuscular Disorders

Dr. M. D. WRIGHT writes from the Research Laboratories of Vitamins Ltd.: On page 420 of the *Journal* of March 16 a short summary is given of the present general opinion of the action of vitamin E in neuromuscular disorders. One admits that the desire to see clinical improvement may perhaps influence some observers into the belief that it is actually taking place, especially where the observations rest upon no objective means of measurement. The fact remains, however, that experimental animal deficiency of vitamin E gives rise to histological and grossly apparent nervous and muscular degenerations, and there is a recent study bearing on this subject, which would appear to be free from the bias mentioned. It is P. Vogt Muller's study on 90 dogs affected with distemper, and the results are best expressed in his own table (*Tierärztliche Rundschau* 1942, 48, 274).

Group	Treatment	No. of Dogs	No. Dying	No. Dying which showed Nervous Complications	No. with Nervous Complications which Survived	Total with Nervous Complications
I	None (controls)	30	14	10	11	21
II	10 mg. tocopherol	30	16	11	12	23
III	5 ml. wheat-germ oil equivalent in vitamin E content to dose given in Group II	30	12	3	2	5

In this case the treatment differed in its effect on the nervous complications according apparently to the form in which it was administered. The result may have been due to something other than vitamin E in the wheat-germ oil, or to some difference in the vitamin itself. In this connexion Harris *et al.* in 1944 (*J. biol. Chem.* 156 (2), 491), showed that α -tocopherol in its natural form was 50% more active biologically than the synthetic *d-l* molecule. Whatever the underlying reason it would appear that certainly in some central nervous system lesions wheat-germ oil has a useful effect.

Intravenous Protein Hydrolysate

Mr. T. M. J. d'Offay writes from the City General Hospital Leicester: Dr. H. E. Magee in his article on nutrition (March 30, p. 475) implies that there is no protein hydrolysate manufactured in this country that is suitable for intravenous use. That is not the position. My colleagues and I at this hospital have during the last six months given "casydrol" intravenously for many types of cases, and continuously for five or six days in many instances, with most satisfactory results. The incidence of thrombosis is no higher than with saline or blood transfusion.

Xenopus Test for Pregnancy

Dr. HUGH DUNLOP (London, W.) writes:—As a constant reader of your instructive "Any Questions?" I note with particular interest your paragraph on the xenopus test for pregnancy (Feb. 16, p. 262). I wish to draw attention to the eponymic title used therein—viz., that of Hogben. So far as I am aware the use of *Xenopus levis* as a test object for pregnancy was first described by C. W. Bellerby (*Nature*, March 31, 1934). So far as I know, Prof. Hogben has never claimed to have carried out any active work on the xenopus test for pregnancy; his work was rather on the ovulation produced by extracts of the anterior pituitary. In these circumstances I cannot believe that Prof. Hogben would wish his distinguished name to be attached to the test.

Proctalgia

ONE MORE writes: May I add my own contribution to "Another Victim" (March 9, p. 380). I would call it a *proctalgia* as it does not appear connected with either coxycy or prostate. In my own case it is always the same—by night, with a commencing dull ache in the anal canal, growing to a sickening intensity, relieved always by the removal of a hard scybalous stool from the rectum. Straining at stool is difficult owing to the pain and to a temporary non-functioning of the sphincters, and so digital removal is the answer. Past experience has shown that the pain will recur very shortly if a small faecal "nodule" is not hooked down from the recto-sigmoidal junction. I think it is a reflex spasm of the internal sphincter with pressure on small internal piles. If constipation is avoided, no attacks occur. The pain is worse than renal colic.

Diagnosis of Amoebiasis: Correction

Dr. E. M. BUZZARD (Oxford) writes: In my letter (April 13, p. 586) I misquoted the paper of Kelsall and Leishman. It should, of course have read "25% of all local admissions for diarrhoea," not "25% of all admissions."

BRITISH MEDICAL JOURNAL

LONDON SATURDAY MAY 4 1946

CROSS-INFECTION IN CHILDREN'S WARDS

A REPORT PRESENTED TO THE BRITISH PAEDIATRIC ASSOCIATION BY THE FOLLOWING
AD HOC COMMITTEE:

Drs. V. D. ALLISON, R. B. BOURDILLON, W. S. CRAIG, Mr. JAMES CROOKS, Drs. W. CROSBIE,
WILFRID GAISFORD, W. GUNN, R. LIGHTWOOD, Prof. J. C. SPENCE, Prof. C. W. VINING, and
Dr. A. G. WATKINS (Chairman)

The term cross-infection is here used to denote any infection acquired by a patient in the hospital environment. Clinically, it is an infection arising during the course of another illness for which the patient was originally admitted to hospital, and may attack the respiratory tract, gastro-intestinal tract, wound, skin, or mucous membrane, or be manifested as one of the specific fevers.

Cross-infection is a constant anxiety to all concerned with the hospital care of sick children and infants, the latter particularly calling for special protective measures. A great deal has yet to be learned. No explanation, for example, has been given for one of its outstanding features—namely, its fortuitous onset. It is well known that, in spite of overcrowding and poor hygiene, one ward may for long be without manifest cross-infection, whereas another which has every facility and is staffed by well-trained nurses may suddenly be the site of a virulent outbreak. In spite of this it would be folly to ignore the value of adequate preventive measures.

Cross-infection which results in nothing more than a mild catarrhal illness, at times apyrexial, must not be dismissed lightly. There is evidence that this may be but the prelude to outbreaks of increasing severity culminating in a series of fatal illnesses. The virulence of the infection may apparently be increased by passage, and unless prompt measures are taken to control the initial outbreak there may be a calamity. Pemphigus neonatorum furnishes an example of this feature. An outbreak may begin with one infant having a single lesion no more than a few millimetres in diameter. Failure immediately to apply protective measures may be followed by the development of pemphigus in successive patients in whom the illness is progressively more severe, ending in a generalized toxæmia.

Cross-infection by infectious fevers, measles, or chicken-pox, for example, seriously hinders the work of a children's department, for such outbreaks necessitate the closure of a ward or wards for an indefinite period.

Whilst a good deal has been written about cross-infection in children's wards, the frequency, extent, and results of this have never been ascertained. In order to provide this information a special *ad hoc* committee was invited by the British Paediatric Association to present its views on the problem, and the Association has instituted an inquiry to collect evidence on the incidence of cross-infection. The obtaining of this evidence will take time, but the results of the inquiry will be published in due course. The report of the Committee which is here presented is a broad statement of our present knowledge on cross-infection, and, although suggestions are made as to how it may be controlled, opinion is still divided on so many points of detail that the report is more in the nature of

a preliminary discussion intended to bring before the profession generally, and those in charge of children's wards in particular, the many problems that have to be faced in the control of cross-infection. This procedure of issuing a report before the exact nature of the problem has been defined may justly be criticized, but it has been done deliberately in this way, in the belief that such a report may help hospital authorities about to create or to improve their facilities for the care of sick children.

General and Bacteriological Considerations

1. Inhalation: Respiratory Tract Infections

This is the most prevalent type of cross-infection, and accounts for much of the morbidity and many of the deaths in infants' and children's wards. It includes tonsillitis, rhinitis, otitis media, common cold, pneumonia, influenza, and infective hepatitis and the specific fevers—scarlet fever, diphtheria, whooping-cough, measles, chicken-pox, rubella, and mumps.

The haemolytic streptococcus, *Str. pyogenes*, which belongs to Lancefield's Group A, is one of the most frequent causes of inhalation cross-infection. Much of our knowledge gained in recent years on the sources and paths of spread of infection in hospital wards is based on studies of the epidemiology and serological typing of streptococcal infections in scarlet fever and measles wards, in otorhinological wards, and in the general medical and surgical wards in children's hospitals and departments. The protean manifestations of infections with *Str. pyogenes* are too well known to need further comment, except to re-emphasize that one and the same serological type may, by spread, cause scarlet fever in one child, tonsillitis in another, otitis in another, and wound infection in yet another, all in the same ward. The importance of the reservoir of *Str. pyogenes* in the human upper respiratory tract as a cause of cross-infection is in part due to the fact that it may have as its portal of entry not only the respiratory tract but also the skin (wound sepsis, infection of burns, erysipelas, impetigo).

The pneumococcus is a not infrequent cause of cross-infection in the respiratory tract, but it does not play such an important part in the epidemiology of hospital infections in this country as it appears to do in the U.S.A., where ward and family outbreaks of acute lobar pneumonia have been reported.

The diphtheria bacillus has been shown to have the same source and mode of spread as infections of the upper respiratory tract with *Str. pyogenes*. Cross-infection with *C. diphtheriae* has been found to be of common occurrence even in diphtheria wards, and, although then without clinical significance, it prolongs the carrier state, with consequent delay in discharge of patients from hospital.

Outbreaks of whooping-cough (*H. pertussis*) are of less frequent occurrence in hospital wards, but may have serious consequences.

The virus diseases are often causes of outbreaks of infection, and are difficult to control. Children with measles are peculiarly susceptible to cross-infection with *Str. pyogenes*, which is commonly responsible for otitis media.

2. Ingestion: Gastro-intestinal Tract Infections

These include gastro-enteritis of infants, epidemic diarrhoea of the newborn, bacillary dysentery (*B. sonnei*), occasionally typhoid or paratyphoid fever, and, more rarely, food-poisoning with *Salmonella* organisms. Thrush, too, may be considered in this group. Outbreaks of gastro-enteritis among infants in hospital wards are common, and may have a case-fatality rate as high as 70%. Although organisms of the dysentery or *Salmonella* group have been identified as the cause of some outbreaks, in most instances no known pathogen has been found, and the possibility that the infection may be due to a virus cannot be dismissed. In this connexion it should be recalled that diarrhoea and vomiting in infancy are often due to infection outside the alimentary tract—notably the upper respiratory tract, especially the middle ears. Thus a child admitted to a ward with a streptococcal or other pyogenic infection—e.g., tonsillitis or otitis media—may by cross-infection produce an upper respiratory infection in another infant, and so cause a parenteral gastro-enteritis.

Outbreaks of typhoid and paratyphoid fevers occasionally occur, but rarely do they arise from infection in the ward. They are more commonly conveyed to the patient in some food infected by a missed case or a carrier among the food-handling staff. It is the nurse who is most in danger of contracting infection from a patient in a ward with an enteric fever.

3. Implantation: Infection of Wounds, Skin, and Mucous Membrane

In surgical wards, otorhinological wards, and wards in which burns are treated, pathogenic bacteria—in particular the pyogenic cocci *Str. pyogenes* and *Staph. aureus*, but also *B. proteus* or *Ps. pyocyanea*—may readily be introduced, either into clean wounds or burns or to lesions already infected, unless the strictest aseptic dressing technique and other precautions are taken to prevent it. The prophylactic and therapeutic use of sulphonamide drugs or penicillin should not be made the occasion for any relaxation in the preventive measure involved in good nursing and aseptic principles. In addition to cases of burns, children after removal of tonsils and adenoids are highly susceptible to infection with *Str. pyogenes* at the operation site, with otitis media or mastoiditis as a not infrequent sequel.

The commonest infections of the skin which may spread in wards are impetigo, ringworm, scabies, and pediculosis. In recent years there seems to have been an increasing incidence of outbreaks of pemphigus neonatorum due to *Staph. aureus* among newly born infants in maternity units and nursing homes, often accompanied by cases of staphylococcal conjunctivitis ("sticky eye"). There is evidence to show that pemphigus neonatorum and staphylococcal conjunctivitis are caused by *Staph. aureus* from the nose or throat or skin of adults in the infants' environment, and it may be a mother, doctor, or nurse, or even a laundress who, through handling napkins or garments with hands infected from the nose or throat or elsewhere, is the source of infection. Moreover, the attendant or parent may be the victim and so become a further source of infection. In outbreaks in infants' nurseries the same serological type of *Staph. aureus* has been isolated not only from skin lesions but also from infants with conjunctivitis in the affected nursery, from the noses of nursing staff, from the dust and air in the nursery, and from the infants' blankets, clothing, and bath. It might also here be mentioned that disinfectants of the liquor chloroxylenolis group, while highly effective against *Str. pyogenes*, are of very little use against staphylococci, and may give a sense of false security if used as hand antiseptics in infants' wards. Mastitis among mothers in maternity units is being noted with increasing frequency, and has been associated with the same epidemiological and bacteriological findings as in pemphigus neonatorum.

The most important infections of mucous membranes, other than those of the upper respiratory tract, which includes the mouth with thrush infection, are vaginitis and conjunctivitis, now less commonly due to the gonococcus.

4. Sources of Infection

The main sources of cross-infection in hospital wards are: (i) Manifest clinical cases. (ii) The patient who is incubating a disease and may be in a highly infectious state. (iii) The ambulant, missed, or subclinical case, unrecognized because of its mildness. (iv) The carrier, who may be convalescent or "healthy." The latter group, which may include both nurses and doctors, is of great importance, as the potential danger can be discovered only by laboratory investigation.

Infection is spread by the secretions, excretions, and discharges of patients, staff, and visitors, and may have its origin in the respiratory tract and its annexes, the gastro-intestinal and urinary tracts, the skin and mucous membrane, septic wounds, burns, or abscesses.

5. Paths of Spread of Infection

These are by contact with contaminated material, either by direct personal contact or by mediate contact with infected clothes, bedding, ward articles, and food. The vectors of infection may be flies. A very important part is played by air-borne infection with droplets, droplet nuclei, and dust, especially in infections having as portals of entry the upper respiratory tract and skin.

It is important to remember (a) that the skin of the fingers and hands, and the hair, may harbour organisms identical with those present in the nose and throat; (b) that the skin of the fingers and hands is particularly liable to contamination with infected material either directly or by contact with infected fomites and dust from furniture and floor; (c) that the pocket-handkerchief, while still the least inconvenient mask against spread of droplet infection from coughing and sneezing, is a vehicle of infection from the upper respiratory tract to the hands and the air.

Droplets and droplet nuclei charged with bacteria are discharged into the air from the nose and mouth, and either settle on the floor, bedclothes, or ward equipment to dry and become redistributed with the dust, or remain suspended as floating particles to be wafted about the ward and inhaled, thereby transmitting infection over a considerable distance. Organisms such as *Str. pyogenes* may remain viable in dust for as long as six months if unexposed to the bactericidal action of sunlight.

Ward Routine

1. Admission of Patients

Every patient should be examined by an experienced medical officer before being allowed to enter the ward. This officer is a key man in the prevention of infection, and his duty should not be left to any medical officer who happens to be available. A history should be obtained of previous infectious diseases, of recent contact with infection, and of immunization. If there is a risk of the patient's bringing an infection into the ward then the urgency of his admission should be reconsidered and, if possible, admission postponed.

Attention must be paid to the throat, nose, ears, and skin; and swabs of the throat should be taken as a routine and, at the discretion of the admitting officer, also of the bowel, skin, and nose. He should direct the admission of the patient to an isolation-room for at least 48 hours if there is the slightest suspicion of infection, or until such time as the patient is declared free from infection. Special admission-wards tend to form a bottle-neck unless there is an adequate number. It is estimated that for an open ward of 20 cots there should be at least four admission-rooms. If isolation-rooms are available for ward nursing, then the number of admission-rooms needed will be less.

If on admission an infection is found to be present which may pass to others in the ward, then the infected child should be admitted only to a closed cubicle or isolation-room. If only an open ward is available the child should be barrier-nursed and placed in the ward as far away from especially susceptible children as possible—e.g., if he has streptococci in his throat he

should not be put near any infants or any cases of rheumatism or nephritis

Type of Case Admitted to Wards.—There is much to be said on clinical and teaching grounds for a unit of medical and surgical cases. There is however a danger in admitting certain types of surgical cases to an open ward because of the risk of wound contamination and because, in turn, an infected wound may be the source of spread of haemolytic streptococci or other infection throughout a ward. Consideration should therefore be given to segregation of special surgical cases—e.g. burns and ear nose and throat cases—those with otorrhoea are a potent source of ward infection, and should always be isolated.

Infants because of their greater susceptibility to cross infection and the more serious effects cross infection may have in them constitute a special problem. No infant under 1 year old should be exposed to infection. Direct infection from ward dust and droplet infection from other children can be prevented only by nursing infants in cubicles or isolation rooms. Even this does not do away with the risk of infection from nurses or faulty management. It is essential, therefore, to admit babies only into isolation rooms or cubicles and to keep them there throughout their stay in hospital. It is an all too familiar tragedy for a healthy baby admitted to hospital for a surgical operation—e.g. pyloric stenosis or hare lip—to die of a gastro-enteritis contracted from ward infection. If, however, only an open ward is available, the infant should be barrier nursed, and by careful spacing and placing of the cots between non infected older children the risk of cross infection may be reduced.

A further point to consider in ward planning is that in the case of babies the admission of the mother may be desirable, either for breast-feeding or to conduct the nursing. Accommodation for this purpose will be necessary, and will be discussed later.

2 Nursing Staff

Next to careful pre admission examination, the quality of nursing is the most important single factor in controlling cross-infection. However ideal the design of a ward may be, it will not achieve its purpose unless the nursing staff is able to carry out its duties with skill and understanding of the problems involved. The sister in charge of a children's ward should, in our opinion, be "children-trained" and hold the RSCN certificate, with fever training as a very desirable addition. She should not have more than 20 acutely sick children under her care. The more the ward is subdivided the heavier are the nursing duties and a children's ward needs more nurses per patient than most other hospital departments. For a ward of 20 beds there should be at least two trained staff nurses for day duty and two for night duty, and the total number of nurses should approximate one per patient for the 24 hours. The practice of leaving only one or two probationer nurses in charge of a ward at night is a common cause of a breakdown in anti infection measures.

Student nurses should be instructed by a pathologist or senior medical officer in the dangers of cross infection and how to avoid them, and should be given simple practical demonstrations in bacteriology. Only by imparting to them a knowledge of the problems involved can one expect their intelligent co operation.

Health of Nurses.—A sick nurse does not do her work well and is a potential source of infection to her patients. All nurses should be encouraged to "report sick" even for minor complaints for the latter may produce a serious condition if passed on to an infant. Sore throats, the common cold, nasal sinusitis, and skin and dental infections are the main dangers that are too often neglected. Gastro-intestinal upsets should also be reported. If a nurse is found to be harbouring infection likely to be dangerous to her charges she should be removed from duty. A medical officer should be responsible for the general health of the nursing staff, and the nurse should have ready access to him. On entering hospital a nurse should undergo a complete examination before acceptance for training. This should include height and weight measurements, history of past infectious diseases, skiagrams of chest, and Mantoux test, Schick test, and blood counts. Repeat examinations should be made every six months, or at any departure from normality. Student nurses should be actively immunized

against diphtheria and the enteric fevers. Nurses previously immunized should be Schick-tested, and, if negative, given a "boosting dose". If positive, they must be fully immunized. Nurses must be taught to keep themselves healthy, many nurses do not make full use of their off-duty periods to take open-air exercise. Facilities for open air games should be provided. Hospitals should accept greater responsibility for the health of their nurses than they have done in the past.

3 Nursing Technique

This has been largely described in the MRC War Memoranda—No. 6, "The Prevention of Hospital Infection of Wounds," and No. 11, "The Control of Cross-Infection in Hospitals"—and only some of the salient features will be mentioned here.

Washing.—Ideally, every member of the nursing and medical staffs, and all students should wash their hands before and after attending to or examining each patient. In practice this is seldom done, but it should be insisted on for every patient who is known to be harbouring infection, and after possible contamination by secretions, excretions, or discharges of any kind. Nurses should "scrub up" before and after attending to the toilet of the mouth or anus of any child as they would when "doing a dressing". Ample and conveniently situated washing facilities must be provided for this purpose. The wearing of rubber gloves may be helpful in preventing soreness of the nurses' hands from frequent washing.

Masks.—Laboratory tests show that impermeable ("cellophane") masks, or masks made of three or more layers of gauze of not fewer than 44 threads per inch, are fairly efficient for preventing dispersal of organisms until the masks themselves become the emitters of bacteria. They must be worn to cover the nose as well as the mouth. Masks must be worn by all attending infants or any child with a wound, and in the latter case the patient himself should wear a mask during dressings. A liberal supply must be provided, for the masks must be changed frequently. When discarded, they should be put immediately into disinfectant solution and left in until washed. In no circumstances should masks be put into pockets or be left lying about.

Gowns.—These should be worn by nurses handling any suspected or known infectious case. They should cover uniforms completely (including the sleeves). A separate gown should be worn for each patient, and after use it should be placed on a peg or stand with its outside outwards.

Dressings.—The technique of ward dressing is fully described in the MRC Memorandum No. 6, referred to above. Dressings done in an open ward are a source of air- and dust borne infections, so that a separate room provided with efficient ventilation and specially equipped for doing dressings and minor surgical procedures should be an essential part of any ward unit.

Napkins.—Destructible napkins are preferable (cellulose or gamgee tissue types). After a baby has been changed they should be immediately placed in a dressing pail and covered with disinfectant, they should then be transferred to a special ward bin and incinerated. If it is not possible to obtain destructible napkins ordinary ones will have to be used. The same ward procedure must be carried out and the napkins taken to the laundry in the ward bin. Napkins should be boiled and washed in a separate machine in the laundry and afterwards handled only with strict attention to cleanliness.

Linen.—Bed linen should not be sorted in the ward, but be sent direct to the laundry. Linen soiled with excreta should be put in disinfectant before being sent. Ordinary washing of "woolies" in the ward by hand is not a guarantee of sterilization, and the use of a disinfectant may be necessary.

Towels.—Nurses and others drying their hands on a communal towel may convey infection to other users. The use of the roller towel is to be condemned, and tissue towelling which can be burnt is the safest, if not the most comfortable, material to use.

Task Nursing.—Many wards have adopted the method of allocating separate tasks to each nurse. Thus one nurse is responsible for the changing of all babies, another for the feeding, and another for dressings. This procedure has much to commend it.

4. Prevention of Infection via Food

The kitchen should be considered as one of the most important departments of a hospital. Wash basins with elbow taps should be provided so that the staff can wash their hands under running water. Ample storage accommodation must be provided for cooked and uncooked food, adequate refrigeration must be available, and all windows fly-proofed. The fly menace should be attacked vigorously by the use of DDT. The kitchen staff must realize the importance of their work and the dangers inherent in unclean methods of handling food.

So far as is possible only those interested in the preparation of food should be chosen for work in the kitchen, and the remuneration paid them should be commensurate with the responsibilities they carry. Work in the kitchen should be considered as the highest level of domestic work in a hospital.

Milk forms the most important part of the dietary in a children's ward. It also forms a perfect culture medium, and especial care must be taken to ensure cleanliness and protection from contamination. The source of supply should be subject to special scrutiny. Frequent samples should be submitted to bacteriological examination. If a sample of the milk is taken on its arrival at the hospital, especially if it be delivered in a churn, and a further sample of the same milk is taken six hours later, useful comparisons can be made. A further useful test is to rinse out the ward vessels with sterile water and examine the rinsing for *B. coli* and other organisms. This test should be carried out on vessels that have been "cleansed" for the reception of milk, and should be done without previous warning. All milk should, of course, be efficiently pasteurized and stored in refrigerators. The use of dried milks overcomes the problem of unsafe liquid milk. It must be remembered, however, that dried milks may be just as easily infected by faulty technique during their preparation as may liquid milk.

A special room should be set aside for the preparation of infants' feeds. Nurses working in the milk kitchen should be specially trained in the dangers of food contamination. They should prepare all feeds under aseptic conditions so far as is possible. Masks and gown should be worn and any nurse with an infection, especially of the bowel—e.g., even a transient diarrhoea—should be kept off duty.

5. Ward Hygiene

The main methods now available for reducing the infective content of air are as follows:

Methods for Removing or Killing Organisms while Air-borne

(a) *Good Ventilation.*—This is of the first importance in reducing air-borne infection. Fresh air in amount equal to 8 to 10 changes per hour should be introduced, although this demands expenditure on heating in winter and needs careful attention to the avoidance of draughts. It is recommended that expert architectural advice be obtained to ensure that existing or proposed wards have satisfactory ventilation and lighting. The fee involved and the cost of alterations are negligible in comparison with the benefit to patients and staff. In all systems of ventilation it is important to arrange the air-flow so as to carry dust and infective particles away from patients rather than towards them. Mechanical systems of ventilation have not always proved satisfactory, and need careful selection and design for the particular conditions present in each building in which they are used. The provision of large windows admitting plenty of daylight is a valuable aid in killing bacteria on the floor and elsewhere in a ward. The interposition of glass does not prevent this effect, although it reduces it. The action occurs even under winter conditions in this country. In this connexion the importance of balcony space should be stressed not only for its own virtues in nursing sick children but because balcony spacing provides extra light and ventilation to the patients. Children should be nursed in the open air as much as possible and, provided they are warmly clad, feverish patients, especially those with respiratory infections, benefit greatly. Ward temperatures should not be above 60° F. (15.6° C.)—except in nurseries for the newborn. To counter low temperature adequate and suitable clothing should be provided rather than artificial heating. Overheating and poor ventilation promote the spread of respiratory infections.

(b) *Adequate Bed-spacing.*—This ranks second in importance only to good ventilation, and the common 6 ft. (1.8 m.) between cot centres is too small. At least 9 ft. (2.75 m.) is needed—and preferably 12 ft. (3.6 m.) Proper bed-spacing goes a long way to reduce droplet infection from case to case. A problem naturally arises here in the question of "extra beds." So far as is possible, the putting up of extra beds should be resisted, but if the emergency does arise then the medical officer in charge must review his bed-positioning and place his extra bed where the risk of cross-infection is minimal, taking into account not only the site of the cot but also its position in regard to the other patients in the ward.

(c) *Use of Ultra-violet Rays.*—Low-pressure mercury-vapour lamps may be used for irradiating the upper portions of hospital wards with ultra-violet rays. They have been tried extensively in America and on a small scale in this country. Provided that there are not too many lamps and that they are removed from direct vision, no goggles need be worn, since normal ceiling paints and

plaster reflect very little U.V.R. The effectiveness of this type of irradiation is greatest in air of low humidity and on freshly emitted moist organisms; dust practically nullifies the bactericidal action of U.V.R. This method is most useful in rooms of a ceiling height not less than 12 ft. (3.6 m.). A portable U.V.R. apparatus of suitable design may prove to be a useful adjuvant when isolation-rooms and furniture.

(d) *Use of Chemical Disinfectants.*—It is easy to disinfect air by chemical treatment under laboratory conditions, but to do this as a continuous routine in hospital wards is troublesome and as yet of uncertain value. Chemical disinfection of air should in the present state of our knowledge of this method be reserved for special occasions or special places, or during epidemics of air-borne disease. The chief disinfectants known to be effective against fresh micro-organisms in concentrations that are harmless or nearly harmless to human beings are: (i) hypochlorous acid; (ii) resorcinol; (iii) propylene glycol; (iv) tri-ethylene glycol; (v) lactic acid.

Methods of Preventing the Re-dispersal of Organisms After Emission and Sedimentation

(a) *Removal of Dust.*—Wards should be designed to prevent dust accumulation. Walls should be smooth, with rounded corners; there should be no horizontal ledges, even at doors; furniture should be built in, with as few movable pieces as possible. Dry dusting and dry sweeping of floors should be prohibited. The most effective method of keeping down dust from floors is the use of spindle oil on floors of wood or linoleum. For floors of terrazzo, cement or asphalt oiling is unsuitable; but wet sweeping, or sweeping with sawdust moistened with calcium chloride, is helpful. Vacuum sweeping is better than dry dusting, although large numbers of organisms pass through the walls of the dust-bag of the ordinary portable domestic sweeper; hence vacuum-sweeping into a centralized piping system is preferable. The time-honoured custom of floor washing with water from a bucket is most unsatisfactory. Special machines which provide a continuous supply of clean water are available, and should be used.

(b) *Oiling of Bedclothes.*—It is now fully proved that ordinary blankets, sheets, pillow-cases, and pyjamas or nightgowns form immense reservoirs of bacteria which are freely scattered in the air when patients move or when beds are made. This emission can be avoided to a large extent by applying a small percentage of a suitable oil—e.g., triton oil—to these articles in the final stages of laundering. Laundries will need expert advice in this matter when this process is first introduced. Dermatitis from the oiling of garments and blankets is not a risk if it is done properly, and this measure alone will greatly reduce the number of bacteria present in a ward.

6. Prevention of Cross-infection by Subdivision of Ward

It follows from the foregoing discussion on air-borne infection that isolation of children in separate rooms must decrease cross-infection. It is on this basis that the subdivision of wards by various types of "cubicles" has been devised. The open ward, however, has certain merits. Children are able to talk and play together, supervision is very much easier, and teaching of students is pleasanter and more practical. In planning a children's ward the aim should be to produce a unit which is designed to reduce cross-infection to a minimum, and which at the same time is practicable to work and will preserve for the child and nursing staff something of the homely, happy atmosphere of the open ward without its attendant dangers.

Individual Isolation Measures

(a) *Isolation Unit.*—The policy of converting wards into isolation units—e.g., by dividing a standard 20-bedded ward into two rows of glass rooms (technically called "cells") with a central service corridor, is not entirely satisfactory. However conscientiously the nursing rules are followed, cross-infection, especially with virus diseases, may occur. The reason for failure is the difficulty in preventing the corridor atmosphere from being a vehicle of infection. Air currents may be reduced, if not completely controlled, by the partial air-conditioning system, or an ultra-violet lamp over each unit door may be used to form a protective screen. Units should be made of glass walls, though the lower 2 ft. (60 cm.) may be of steel or wood. In building, care must be taken to avoid horizontal ledges where dust may settle in the junction between the steel and the glass. Glass allows children to see their neighbours and thus reduces their sense of loneliness and, of course, allows easier nursing supervision. Each unit must have good daylight, ventilation, and heating. Its size must be such that a bed or cot can be moved in and out easily and that there is plenty of room for all nursing attention and for minor operative procedures—e.g., lumbar puncture. Doors should be capable of being opened by elbow or foot, not by hand. Every unit should, ideally, be provided with its own wash-basin, but in the interests of economy these may have to be situated

in the corridor, and one basin may have to serve for more than one infant. When each can be fitted with its own wash basin, the latter should be of such a design that it may be used for bathing a baby as well as for nurses' hand washing. Infants should not be bathed in a communal bath, which may convey infection.

(b) *Cubicles*—By these are meant ward divisions by partitions not reaching to the ceiling and varying from 7 to 9 ft (2.1 to 2.75 m) in height. For small babies this method may be satisfactory, but with older children, who may stand on their cots, even 9 ft is barely high enough. Cubicles have the great advantage of being cheaper to build than separate rooms, and their open tops allow of easier ventilation. Opinion is divided on their value as compared with separate rooms or cells, and, although they may give a sense of false security, they at least indicate to the nurse and doctor the need of care.

(c) *Complete isolation room*—Children, even babies, dislike being by themselves. The size and equipment of such rooms should be as described for isolation units. Ideally, the front should face south or south west, and be provided with a verandah or balcony, with french windows opening upon them, so that cots can be wheeled out. Outside partitions, which are theoretically necessary, are unsightly, and may be entirely, or in part, dispensed with provided patients occupying the verandah at the same time are carefully selected and spaced. If several floors are used, lifts must be provided and adequate measures taken to ensure that children cannot climb out of windows or over balcony walls or railings. If conversion of an existing ward to include cubicles or rooms for isolation be contemplated certain considerations are necessary before deciding on the required number. The patient most in danger from cross infection is the infant, and as he is less likely to resist the company of other children he should be specially considered. All babies under 1 year old should be nursed in isolation. So far as accommodation permits, the age limit for isolation should be raised to 2 years, but for older children it should be reserved for pre-maternal observation on admission, children with suspected or proved infection, and the very ill child to whom a cross infection might be fatal. In subdividing an open ward some space will be lost and the number of beds reduced. This loss of beds must be set against the lessened risk of infection, with a shorter hospital stay, so that the annual admission rate will not be reduced. The actual number of isolation cells needed per ward will vary with the type and age of case admitted, but at least 25% of the beds should be isolated.

7. Other Desiderata in a Ward Unit

In planning a ward unit other facilities not hitherto stressed must be provided, all of which have a direct or indirect bearing on the question of cross infection. These are:

(a) *Separate Room for carrying out Special Procedures*—Dressings and minor procedures of a septic character should never be carried out in an open ward where wound contamination is likely. A special efficiently ventilated room should be set aside for this purpose, to which the children can be taken. The room should be considered as an operating theatre, with all its associated aseptic techniques practised.

(b) *Accommodation for Mothers*—In the case of mothers feeding their babies at the breast, provision must be made for them to live in the hospital so that breast feeding can be maintained—in itself a most valuable measure against cross infection. The practice of admitting mothers to live with and conduct the nursing of their babies, whether breast- or bottle fed, has much to commend it. Accommodation should therefore be provided for this purpose. It is desirable to have available specially designed flats or houses where mothers can live with their babies.

(c) *Accommodation for Parents*—Parents are naturally anxious to be at hand if their children are seriously ill, and accommodation for them should be available.

(d) *Provision for Examination of Out patients*—From time to time children are brought to the ward unit for examination but not necessarily for admission. This is not a good policy, but if it must be done there should be a separate waiting room and examination-room which will prevent the introduction of infection from outside.

NUTRITION IN VIENNA IN NOVEMBER, 1945

BY

MAGNUS PYKE, Ph.D., F.R.I.C.

A report has already been made on nutrition in Vienna in early September, 1945 (Pyke, 1945). At that time, although the Allied Council had been established, adequate food rations were not being distributed in the city. On Sept. 23, however, it was decided that rations providing at least the minimum nourishment needed for subsistence should be distributed throughout Vienna. At first, although similar rations were issued in different parts of the city, each national element comprising the Allied Council brought in supplies for the feeding only of that population living in the sector of Vienna administered by itself. At the beginning of October, however, it was agreed to pool all food, so that the Austrian authorities could distribute as nearly as possible the same ration throughout Vienna.

Although the Allied Council ration scales represented a substantial improvement on those previously obtainable in the city, they were only sufficient to provide a bare nutritional minimum. Furthermore, the provision of vitamin C and vitamin A was entirely dependent on potatoes and vegetables, supplies of which were uncertain, and in addition, so far as children and pregnant women were concerned, the adequacy of the diet was contingent on at least a minimum amount of milk being available. A further overall weakness of all the ration scales was a shortage of calcium.

As was inevitable in the light of the uncertain and divided administration of Vienna, in the event, exact standardization of the ration was not found to be completely possible. The fact that supplies during the two weeks covered by the survey were greater or less in one zone than in another is probably not significant. The difficulties of food distribution made it impossible for issues to be equal at all times. For example, during the first week there was a double issue of fat in the Russian sector. This was made to compensate for a failure to distribute fat during the previous week.

Individual Food Consumption

In Vienna a number of factors are likely to affect the composition of the diet eaten by an individual. Although the nature of the food is broadly contingent upon the composition of the ration there are, besides the general fact that rations are taken into a household and not usually eaten by an individual, the influence of communal meals on the diet and the availability of unrationed foods from gardens or from the black market. A further possibility is that rationed foods may be exchanged for clothes or other goods. In order to assess the composition of the diet actually being eaten by different sections of the Viennese population in November, 1945, a number of groups of individuals were interrogated about the food they had eaten during the previous 24 hours. The assessment of the nutritional value of the diet was made in the same manner as that described in the previous report, written in September.

Normal Consumers

Two groups of normal consumers were investigated. These were taken at random from queues in public offices in the XIth and XIIIth districts. The composition of the diets eaten, as derived from calculations made on the data collected, is shown in Table I.

TABLE I—Composition of the Average Daily Diet Eaten by Normal Consumers in Vienna Nov. 7-16, 1945

	Cal	Prot (g)	Fat (g)	Ca (mg)	Fe (mg)	Vit A (i.u.)	Vit B (mg)	Rib. Acid (mg)	Vit. C (mg)
Bz. XII (15 people 7 men, 8 women)	1,630	59	18	190	17	220	1.70	0.75	11
Bz. XIII (20 people 9 men, 11 women)	1,750	60	16	240	17	130	1.70	0.70	10

NOTE.—A deduction has been made to allow for the loss of vitamin C in cooking.

After 30 years' service in providing the more severely wounded ex-Service men with the means of living a useful life in the community, the Princess Louise Scottish Hospital for Maimed and Limbless Sailors and Soldiers has decided to build a modern hospital on the site of its present establishment at Erskine, on Clydeside. In the years 1939-45 approximately 3,000 men from Scottish regiments, the Royal Artillery, Royal Engineers, Royal Marines, Royal Navy, and Merchant Navy were admitted to the hospital. There are now 148 patients, some of them armen, including 63 surgical, 42 medical, 38 paraplegic, and there are also 64 pensioners. The hospital appeals to the people of Scotland to help to replace the present buildings erected shortly after 1916.

It is interesting to compare the figures shown in Table I with those obtained in September from two similar groups of individuals. In September the calorific value of the diet was about 1,000 and the food eaten provided less than 50 g. of protein. Moreover, in the earlier survey, whereas one of the groups of individuals studied was obtaining about 50 mg. of vitamin C per day, the other received only 7 mg. The present more equal vitamin C intake is due to the improved distribution of potatoes. The lack of calcium and riboflavin still apparent is due to the overall shortage of dairy produce and to delay by the Austrian authorities in carrying out a Kommendatura agreement that flour might be fortified with chalk. The shortage of vitamin A is largely due to the lack of green vegetables.

Factory Workers

Groups of industrial workers from two different Bezirke were surveyed. The first factory visited was a light engineering works in the XIIth district employing a large number of men. The second was a smaller establishment in the XIVth district manufacturing heating appliances. At both factories a canteen meal was provided at midday. In order to obtain this meal work-people must give up a certain number of ration coupons. The amount of food they receive in return, however, is almost always considerably larger than that represented by the coupons. The advantage for the canteen meals is partly obtained by the official issue of a *per capita* supplement. Of far greater importance, however, is the fact that almost all factories use part of their output and, even more significant, part of their transport to obtain by one means or another potatoes, horse meat, or some other additional supply of food frequently from sources outside Vienna. In the case of the two factories where studies were carried out, the midday meals provided approximately 910 and 870 calories respectively. The nutritional value of the full day's diet eaten by the workmen at the two factories is shown in Table II.

TABLE II.—Composition of the Average Daily Diet Eaten by Factory Workers in Vienna, Nov. 7-14, 1945

	Cal.	Prot. (g.)	Fat (g.)	Ca (mg.)	Fe (mg.)	Vit. A (i.u.)	Vit. B ₁ (mg.)	Rib. (mg.)	Nic. Acid (mg.)	Vit. C (mg.)
Light engineers, Bz. XII (group of 20 men)	2,300	90	32	390	23	810	2.50	1.22	16	46
Heating-appliance manufacture, Bz. XIV (20 men)	2,040	84	16	300	26	120	2.25	1.01	12	19

NOTE.—A deduction has been made to allow for the loss of vitamin C in cooking.

The figures in Table I suggest that normal consumers, whose ration provides about 1,550 calories, were eating somewhat more than the food to which they were strictly entitled. In the case of factory workers, however, most of whom possessed workers' rations supplying 2,250 calories, there is some evidence to suggest that part of their food entitlement went to their families. The figures in Table II show that the food eaten by the two groups of men studied was not enough for them to be able to do physical work efficiently, even though an improvement was apparent over the far more inadequate food intake of about 1,500 calories found during the course of the survey made in early September. In addition to the overall shortage of food shown by the lack of calories, the diet of these factory workers was deficient in calcium and vitamin A and to some extent also in riboflavin. An outstanding feature of the Viennese factory workers is the substantial contribution made by the factory meal. Since a large proportion of this meal is derived from foods which are obtained in a somewhat unofficial manner, the nutritional safety of this class of the community may be even less secure than would appear to be the case.

Children

The diets of the groups of boys and girls about 12 years old were investigated in two separate schools. At the time this investigation was made, although the official ration provided for the issue of half a litre of milk to children between the ages of 6 and 12, in fact no milk at all was available for this age group. Since the September survey was carried out, how-

ever, the municipal authorities have been able to provide day meals for almost all the children attending school in Vienna. These meals are in most cases cooked centrally and issued to the schools in insulated containers. The food provided tributes about 380 calories a day during six days of the week. At the schools where this investigation was carried out rotation of meals was customarily made up by bean soup, soup, flour soup, barley soup, and potato soup, together with a roll. A small amount of dried milk in certain of the meals provided a limited contribution of animal protein. During investigation it appeared that the children usually ate the food provided at school and then were given another when they returned home.

TABLE III.—Composition of the Average Daily Diet Eaten by School Children in Vienna, Nov. 9-14, 1945

	Cal.	Prot. (g.)	Fat (g.)	Ca (mg.)	Fe (mg.)	Vit. A (i.u.)	Vit. B ₁ (mg.)	Rib. (mg.)	Nic. Acid (mg.)
A group of 15 girls aged 12-13, Bz. XII	1,810	76	19	320	21	660	1.88	0.85	10
A group of 15 boys aged 10-12, Bz. XII	1,820	76	29	360	19	750	1.89	1.10	10
A group of 20 girls aged 12, Bz. XII	2,240	89	28	560	21	2,240	2.0	1.09	11
A group of 20 boys aged 12, Bz. XII	1,880	80	18	380	20	2,390	1.74	0.94	11

NOTE.—A deduction has been made to allow for the loss of vitamin C in cooking.

The figures given in Table III show that although the value of food available to children has been substantially increased from about 1,300 calories available early in September, it still falls short of the approximate requirement of 2,500 needed for proper development. Furthermore, it is substantially deficient in calcium. There is also a deficiency of vitamin A, together with a shortage of vitamin B₁ and riboflavin. The marked fluctuation in the vitamin A in the different groups of children is due to the uneven availability of green vegetables. In the case of the last group of 20 out of the 20 had eaten substantial amounts of green vegetables during the period of survey and others had only eaten vegetables shortly before. At the first school, however, the children had had only small amounts of cabbage and many of the others were unable to recall when green vegetables had last been available to them.

Family Food Consumption

In order to obtain a picture of the availability of food in the different sectors of Vienna a survey of family food consumption was undertaken. During each of five consecutive weeks approximately ten families in the four residential sectors and in the international sector of Vienna were daily by welfare workers specially detailed for the investigation by the Jugendamt. At the first visit an inventory was taken of the food in the larder which would be used in the course of the week. Each item was weighed and a record made. The following seven consecutive days, a visit was made to each household, and all foods purchased or otherwise obtained entered on a record sheet. In order to check the accuracy of the information provided by the housewives, daily menus were recorded on at least two days of the survey. The collected menus served a twofold purpose—first, it gave information to how rationed items were being used, and, secondly, it was to bring to light foods which by oversight or otherwise had not been recorded. On the seventh day a final inventory was taken of food remaining in the house.

As has been previously mentioned, a number of meals were eaten outside the house in Vienna. In order that the *per capita* consumption of food could be calculated from the total amount of foods coming into each household, it was assumed that each individual could be represented by 21 meals per week. Should three individuals record that 7 meals per week were obtained from a factory kitchen, a deduction of one meal was made in assessing the *per capita* family food intake. Dinners, however, were assessed as only half a meal, since

have said, it was customary for children to eat another meal when they reached home. Besides making an allowance for meals taken out of the house, an opposite allowance was made when guests were recorded as having taken meals with the family.

It had been planned that families should be chosen for the survey entirely at random, and addresses were so selected from the house lists used by the Food Office for the issue of ration cards. When the survey was begun, however, some difficulty was encountered in obtaining co-operation from all households, many of the Vienna population have suffered annoyance and hardship from a series of visits from billeting officers, requisitioning officers, and the troops of several nationalities. Details of the population sample finally included in the survey are given in Table IV. It can be seen from this table that the sample is considerably overweighted with women. The proportion of men to women in the whole of Vienna at the time the investigation was 40 to 60.

TABLE IV.—Composition of the Population included in the Survey of Family Food Consumption

Number of Households			
British sector	..	20	
American sector	..	19	
French sector	..	20	
Russian sector	..	18	
International sector	..	20	
Total	..	97	

Number of Individuals

General consumers	26	103	134
Employees	18	43	66
Workers	19	11	30
Day workers	2	4	6
Children:			
2-5 years	—	—	13
5-6	—	—	17
6-12	—	—	32
Total			295

A most interesting feature is the list of vegetables obtainable in the separate zones of Vienna. Officially, only potatoes had been issued during the period of the survey, with the exception of a small amount of green vegetables in the Russian zone during the first week. The data collected, however, showed that a useful supply of green vegetables was being obtained as gifts or by individual purchases in all sections of the town. It seemed clear that, although many families could obtain vegetables, a substantial number of others were without them for prolonged periods.

The average nutritional value of the foods obtained by Vienna households in different parts of the city between Nov. 7 and Nov. 23, 1945, is given in Table V. In comparing the results shown in this table with those in Tables I-III it must be borne in mind that the latter gave an estimate of the amounts of food which people had actually eaten, whereas Table V shows the average amounts of food obtained per head in each household. It is often considered that under normal circumstances a loss mounting to up to 10% of the nutritional value occurs during the process of preparation and cooking. It might therefore be argued that the results of the household survey ought not to be compared directly with those of the individual survey. On the other hand, the overall scarcity of food in Vienna might be expected to cause a reduction in the margin between the results obtained by the two methods.

The results set out in Table V based on family food consumption are, in fact, in substantial agreement with the studies of the individual groups composing the family summarized in Tables I-III. The average figures shown in Table V indicate, as did the previous figures, that, although the total amount of food available to people in Vienna, measured by its calorific value, is not sufficient to provide a diet fully adequate nutritionally, it nevertheless reaches the *per capita* value of 3,000 calories, which might reasonably be expected to be sufficient for subsistence. The two consistent deficiencies in the diet are a deficiency of calcium and a deficiency of vitamin A. In addition to these shortages there is some

deficiency in riboflavin. A fourth weakness in the diet is a tendency to a deficiency in vitamin C. It must be remembered that whereas a deduction to allow for the loss of vitamin C in cooking has been made in Tables I-III, no such allowance has been made in Table V. Since the loss of vitamin C in cooking amounts to about 60% for green vegetables and 50% for potatoes, it is highly probable that not enough is available for

TABLE V.—Average Nutritional Value of Food obtained per Head per Day by Vienna Households (November, 1945)

full nutrition. Furthermore, it has already been pointed out that the distribution of green vegetables is unequal between different families in different parts of Vienna.

Loss of Weight among the Population of Vienna

During the past three months the heights and weights of several groups of the population in Vienna have been collected. Figures for children and for male factory-workers are set out graphically in Fig. 1 and Fig. 2 respectively. The children's weights were collected by the Vienna school medical service; the weights of factory-workers were specially obtained as part of this investigation.

Children

In Fig. 1 the heights and weights of 6,858 Viennese children have been plotted. The standard curves shown are those of Piquet (1913). From this graph it can be seen that in October

FIG. 1.—Heights and weights of Vienna school-children, Sept.-Oct., 1945. — = Average recorded height/weight of 6,858 children. . . . = Piquet's standard.

the children of Vienna showed no loss of weight compared with the standard. There was, however, some increase in height without a corresponding increase in weight. In general, however, the results appeared to be reassuring. It is interesting to record that a similar set of weighings carried out in Graz, in Styria, gave results almost identical with those obtained from the Vienna school-children.

FIG. 2.—Heights and weights of male factory workers in Vienna, 1945. (The standard for body weight is that of Davidson and Anderson.)

Industrial Workers

In Fig. 2 the body weights of workers in a large factory in the XIth district of Vienna have been plotted against heights. The total of approximately 600 workers were split into the three age groups shown. The figures used as standard for body weight are those of Davidson and Anderson (1940). The first part of Fig. 2 suggests that in September a loss of weight between 8 and 10 kg. had occurred, with the greater loss having been suffered by the older men. The second part of the figure indicates that by November the youngest group of men had attained a weight equal to the standard, while in all cases an increase had occurred. Although weighings were carried out with the work-people in shirt and trousers and without shoes, we cannot completely exclude the possibility of an increase in weight due to heavier underclothes worn in the colder weather.

Conclusions

Although there was a substantial improvement in the food supplies of Vienna between September and November, 1945, the full nutritional requirements have not yet been provided. So far as protein is concerned the total amount available appears to be adequate except for the lowest ration category of "normal consumer," although it is possible that the proportion of animal protein may be insufficient. The shortage of fat in the diet, although perhaps of little physiological significance, is a measure at least of unpalatability.

A comparison of the intake of vitamins A and C in September and November is of interest. In the earlier month the official ration supplied no vitamin A or vitamin C at all, but, since people could procure at least a small amount of vegetables for themselves, their diet was partially protected. In November, however, the official ration was designed to supply adequate quantities, but as potatoes were scarce and vegetables almost unobtainable, the actual diet available was worse than before. In order, at least in part, to make good this deficiency the British authorities are proposing to issue vitamin tablets throughout their sector. These tablets will also supply a supplement of riboflavin. To meet the calcium deficiency it is proposed, as was mentioned earlier, to add chalk to the bread.

Summary

A dietary survey carried out in Vienna in November, 1945, showed that the food eaten by normal consumers provided about 1,700 calories daily; factory workers obtained approximately 2,200 calories, and children 10 years old about 2,000 calories. All the diets were deficient in calcium, vitamin A, and riboflavin, and there was a shortage of vitamin C for the children. A survey of the weekly food consumption of 97 Vienna families broadly confirmed these results and suggested that the average *per capita* diet supplied about 2,000 calories daily.

The weights of Vienna school-children showed no drop below the standard for age, while a slight excess in height appeared to exist. A group of factory workers seemed to have increased in weight since September.

THE "IONIZATION" OF PENICILLIN

BY

J. L. HAMILTON-PATERSON, M.D.

Pathologist, Redhill County Hospital, Edgware

The practice of using solutions of penicillin for the treatment of infected wounds by ionization seems to be on the increase and some authors—notably von Sallmann (1943), Struble and Bellows (1944), and Dunnington and von Sallmann (1944) using this method for eye infections have claimed satisfactory results. Before these results can be accepted it must be shown that penicillin in solution behaves as an electrolyte. A series of experiments was therefore designed to test this hypothesis and the results, which are reported in this paper, suggest that it is untenable. No attempt was made to determine the specific conductivity of penicillin in solution, but it seems amply clear that, even if the molecule does move, the rate will be so slow that a therapeutic concentration in the tissues will not be obtained, and there is a strong possibility that the penicillin will be destroyed by the products of electrolysis of other electrolytes present.

Methods

In all experiments the apparatus shown in Fig. 1 was used. The strength of the penicillin solutions was between 25 and 50 units per ml.—a convenient concentration for estimation by the cup method employed; where a penicillin-agar base was used, slices were cut off and dropped on to seeded plates and the penicillin content estimated from the diameter of the zone of inhibition, as in the cup method.

Where an indicator was required B.D.H. 4110 was used, as this dye has no inhibitory effect on penicillin. All the water employed in the experiments was redistilled from alkaline KMnO_4 in an all-glass apparatus.

Experiment 1.—The glass tube was filled with the redistilled water. The maximum current was passed for two hours. During this time the current increased from 0.05 to 0.15 milliampere. The test was

repeated with a solution of sodium penicillin in redistilled water (25 units per ml.). The milliammeter readings increased from 0.10 to 0.15 in two hours.

Fig. 1.—Apparatus used for all experiments.—A, A', Non-polarizable platinum electrodes, 14 cm. apart. B, Glass tube, 1 cm. bore. C, Holes in tube for sampling. D, Thermometer. E, Variable resistance for controlling current. F, High-tension battery, 240 volts. G, Milliammeter.

The addition of penicillin to the water leads to only a slight initial increase in the amount of current passing through it. Penicillin is therefore either a very poor conductor or a non-conductor; in the latter case the slight increase in current might well be due to impurities in the drug.

Experiment 2.—The glass tube was filled with sodium penicillin solution (25 units per ml.) and the maximum current passed for two hours. Samples of the solution from the region of the anode and

Fig. 2.—Experiment 2: showing rate of loss of penicillin at the anode (+) and cathode (-). Aqueous solution; two tests.

of the cathode were tested for penicillin activity at intervals. The results of two tests are shown in Fig. 2, where it can be seen that the penicillin is destroyed at both electrodes, although more rapidly at the cathode.

Experiment 3.—Experiment 2 was repeated with addition of the indicator, B.D.H. 4110, to the solution. The colour changes showed that the solution at the anode rapidly became acid (pH 4) and at the cathode became alkaline (pH 10). At the end of 15 minutes these changes were complete in the respective halves of the tube. Test sampling from each end of the tube for penicillin activity was carried out, and the results obtained were identical with those of Experiment 2.

The indicator therefore has no effect on the penicillin. The destruction of the penicillin is probably due to the gross pH changes in the solution, which themselves may be due to the electrolysis of impurities in the penicillin.

Experiment 4.—In order to slow down the rapid ionic movement demonstrated by the pH changes in Experiment 3, the tube was filled with 3% agar in redistilled water containing B.D.H. 4110 and 50 units of sodium penicillin per ml. The current was maintained at 10 mA for 23 minutes. The agar column was 120 mm. long, and at the end of the experiment the colour change at the anode indicating pH 4 was 35 mm. long and at the cathode (pH 10) 20 mm. long. Plating of disks of the agar at the end of the experiment showed that at the anode, where the pH was reduced to 4, only 3 units penicillin per ml. remained, and at the cathode only traces of penicillin were detected. In the central part of the column, where the reaction remained neutral, 50 units per ml. were recoverable from all parts, no shifting

towards either electrode being demonstrated. This experiment again suggests that the penicillin destruction, when it occurs, is due to gross pH changes.

In none of the foregoing experiments do the conditions of test resemble those which would be encountered in *in vivo* methods. As practically all body fluids contain sodium chloride and most tissues other chlorides, the experiments were repeated in the presence of the former salt, and, as will be shown, this leads to even more rapid destruction of the penicillin.

Experiment 5.—The tube was filled with 0.9% NaCl in redistilled water containing various concentrations of sodium penicillin. These were subjected to various strengths of current, and the penicillin content was determined at intervals by the cup method, as in the previous experiments. The results are shown in Fig. 3. It will be

Fig. 3.—Experiment 5: solutions of penicillin in saline. Showing rate of loss of penicillin at anode (+) and cathode (-) at different current strengths.

seen that the penicillin is destroyed more rapidly at the anode (in watery solutions the reverse is true), and this is probably due to the presence of chlorine. Also the greater the current the greater the rate of destruction of penicillin. For instance, at 20 mA 20 units per ml. are destroyed within 10 minutes (anode), while at 5 mA 20 units per ml. are destroyed in 30 minutes (anode). The tests also show that the rate of destruction of penicillin in a solution of NaCl is more rapid than when no NaCl is present. The temperature of the solution being ionized rose in all these tests but never exceeded 21° C.

Experiment 6.—The tube was filled with a column of agar containing 0.9% NaCl, 50 units per ml. of sodium penicillin, and indicator B.D.H. 4110. The current was passed at 10 mA for 20 minutes, and at the end of this time the agar was sliced and plated. The penicillin had been completely destroyed where colour changes had occurred in the agar, but in the central part of the column, where the pH was about 7, there had been no detectable loss or movement of penicillin.

Compared with Experiment 4 these results show that ionization in agar containing penicillin and NaCl leads to more rapid destruction of the penicillin in the region of the electrodes. Again there is no evidence that penicillin behaves as an electrolyte.

Discussion

No claim is made that these experiments are exhaustive, but the results seem to justify an assumption that any attempts to ionize penicillin into the body are doomed to failure. Penicillin appears to be either a very poor conductor or a non-conductor—an observation confirmed by the failure to demonstrate any movement of penicillin during the passage of an electric current through a solution of its sodium salt. If penicillin is a conductor, albeit a very poor one, it should be possible to demonstrate ionic movement by suitable *in vitro* experiments; even if this can be done the movement will be relatively slow, and it is doubtful whether a therapeutic concentration could ever be obtained in the tissues. Again, all tissue fluids contain sodium chloride, and, as has been shown *in vitro*, the products of electrolysis of this salt are highly lethal to penicillin; naturally free chlorine and sodium hydroxide are not formed in the tissues during electrolysis, and at the moment one cannot

say whether the experimental results *in vitro*, in this respect, are applicable to *in vivo* methods.

High concentrations of penicillin were not used in the experiments because they would have had to be grossly diluted in order to estimate the amounts present. This dilution would have introduced unnecessary errors into the estimations.

Summary

Penicillin is either a non-conductor or a very poor conductor (Experiment 1).

It has been impossible, in the conditions described, to demonstrate any movement of penicillin under the influence of an electric current (Experiments 2 and 6).

The presence of the products of electrolysis of sodium chloride in the *in vitro* experiments led to the rapid destruction of penicillin. It is not known how far this observation can be applied to *in vivo* methods.

DIFFERENCE IN THE EFFECT OF SCOPOLAMINE ON PERORAL AND SUBCUTANEOUS ADMINISTRATION

BY

Prof. SVEND LOMHOLT, O.B.E., M.D.

Chief of the Skin Clinic of the Finsen Institute, Copenhagen

Particular circumstances brought it about that in my department (dermatology) we had occasion to carry out a series of systematic studies on the effect of scopolamine given by mouth in doses of 3-4 mg.—i.e., 6 to 8 times the Danish maximal dose (0.5 mg.)—and to compare it with the effect of 0.5 mg. given subcutaneously.

Effect of 3-4 mg. Given by Mouth

One of my patients, a nurse admitted for a severe x-ray burn had some time before been sentenced to prison for an attempt to poison her mother, being accused of having poured some scopolamine in her coffee. The sentence aroused an enormous sensation in Denmark, and many persons offered voluntarily to act as experimental subjects in order to try out the effect of scopolamine given in moderately increased doses by mouth (3-4 mg.). This was the amount of scopolamine with which the attempt at poisoning was claimed to have been made. An experiment with the peroral administration of 10-15 mg. to the sentenced woman had given merely moderate, not serious, symptoms of the well-known type, and hence further experiments were to be looked upon as safe. In the literature no instance of death from ingestion of scopolamine has been reported—not even with doses as high as 500 mg. and 300 mg.

The 30 persons employed for these experiments were chiefly nurses, aged from 30 to 60. In the majority of the subjects the only noticeable symptom was a moderate dryness of the mucous membranes accompanied by some drowsiness. The development and intensity of the symptoms may be recorded summarily as follows. In no instance was a stronger effect observed.

1. *Heart Action*.—After 15 to 30 minutes a moderate fall in the pulse rate appeared, often accompanied by a minor rise in the rate of respiration.

2. *Mucous Membranes*.—After 30 to 40 minutes a distinct dryness of the mucous membranes of the mouth and throat was noticed.

3. *Muscles*.—After a moderate laxity of the muscles was observed. Convulsions or rigidity were not seen in any instance. A couple of subjects stated, however, that they had some slight jerky contractions in the legs.

4. *Pupils*.—Dilatation of the pupils is said to be the most characteristic symptom of scopolamine action, and hence the subjects were examined very closely for the appearance of this symptom at intervals of 15 minutes. In 10 cases no distinct dilatation could be demonstrated; in 3 cases only, this phenomenon reached a consider-

able size (7.5 mm.)—after about two hours—and was accompanied by lowered reaction to light. The dilatation of the pupils was but slowly.

5. *Sensorium*.—The action on the sensorium was limited to a slight drowsiness in some subjects. The two oldest, aged 69 and 65, sent a slight degree of excitation, with loquacity and actions resembling that seen in moderate alcoholic intoxication.

6. *After-effects*.—Most of the subjects noticed no after-effects at all and slept well during the following night. A few felt a little tired next day, and two noticed a slight dryness of the throat. On the following day a moderate dilatation of the pupils could still be demonstrated in a few of the subjects examined.

After this experiment 4 additional persons were given 4 mg. of scopolamine by mouth. The symptoms were not particularly more pronounced than in the preceding group.

Peroral and Subcutaneous Methods Compared

It was most interesting to compare the features of intoxication here observed when the same subjects were given a subcutaneous injection of 0.5 mg. of scopolamine. In this way it became practicable to settle the question about the proportional effect of scopolamine given perorally and subcutaneously. These experiments were carried out on 14 persons. Only two of them showed an effect of scopolamine identical with that observed after ingestion of 3 mg., perhaps even a little weaker. In the remaining 10 subjects the effect was distinctly stronger after injection of the remedy, in most of the cases even considerably stronger, and it appeared more rapidly too, showing the following picture:

1. The pulse rate and the frequency of respiration were not influenced much more strongly here, but the effect appeared sooner.

2. The dryness of the mucous membranes was noticeably more pronounced, in several cases even much more pronounced—so that, for instance, the subject could not swallow a biscuit without making of water.

3. Also the effect on the musculature was greater here, and in several subjects it was so marked that it was difficult for them to keep on their feet.

4. Dilatation of the pupil was quite distinct in 8 of the 10 subjects, and impairment of the reactivity of the pupil was demonstrable in 7 cases, considerable in 2.

5. Drowsiness and sleepiness appeared in nearly all the subjects, often accompanied by an inconveniencing dizziness. Symptoms of excitation and confusion were observed in 4 subjects. As mentioned already, the character of this symptom was that of a "drunk." A couple of subjects had slight hallucinations. The symptoms of excitation always made their appearance rather late—at the earliest after two hours.

6. Also the after-effects were decidedly stronger after subcutaneous injection than after ingestion.

Later two of the nurses who had been given 4 mg. of scopolamine by mouth were submitted to an additional test for the effect of 0.5 mg. of the remedy injected subcutaneously. The effect here was about the same as that observed in the 12 subjects first examined.

If we wish to give a numerical expression for the decrease in the effect when scopolamine is given per os instead of subcutaneously, it is obvious that on an average the effect then is at least 6 times weaker, or rather, perhaps, 8 times weaker.

Conclusion and Summary

The effect of 3 or 4 mg. of scopolamine given by mouth to healthy adult subjects was generally rather weak—much weaker than would be expected *a priori* according to the doses officially established as maximal for peroral administration. In a majority of the subjects the effect has to be characterized as insignificant, as chiefly it was limited to a slight dryness of the mucous membranes of the mouth and throat.

A comparative study was made of the variation in the effect of scopolamine when given subcutaneously and per os to 14 of the same persons. The doses here employed were 0.5 mg. given subcutaneously and 3 mg. (in two cases 4 mg.) given by mouth. In 12 cases the effect of 0.5 mg. injected subcutaneously was stronger than in several cases decidedly stronger—than that of 3 or 4 mg. given by mouth. In only two cases was the effect of 3 mg. per os equal to or perhaps a little stronger than that of 0.5 mg. given subcutaneously.

Judging from these results the efficacy of the drug given by mouth may be reckoned on an average to be about one-eighth of its effect when injected subcutaneously.

* For further details see *Nordiskt Med.*, 1944, 20, 793.

Its low toxicity when given per os calls for a revision of the maximum dose of scopolamine—and probably of some other alkaloids too—as fixed by the official pharmacopoeias.

In forensic medicine the consequence will be that no injury can be foreseen from a dose of 3 to 4 mg. of scopolamine given by mouth. (It was only after 8 years that the nurse was taken before a higher court and, on the basis of this investigation, rehabilitated.)

In all the experimental subjects here employed the symptoms characteristic of scopolamine effects were observed to make their appearance in the same chronological sequence: (1) After 15 to 30 minutes, reduction in the rates of the pulse and respiration. (2) After 30 to 45 minutes, dryness of the mucous membranes of the mouth, nose, and throat; a little later, moderate muscular atony and moderate drowsiness. (3) Pronounced dilatation of the pupils was seen only in a minority of the cases—generally beginning after 60 minutes and reaching its maximum after 120 minutes. (4) Symptoms of excitation were seen in a few cases, especially elderly persons, but not until 120 minutes after ingestion of the drug.

After subcutaneous injections of 0.5 mg. the sequence of the symptoms was the same as after peroral administration, but their development was somewhat more rapid and their intensity more pronounced.

CARCINOMA OF THE RECTUM IN SISTERS

BY

R. E. REWELL, M.D., M.R.C.P.

(From the Department of Pathology, Guy's Hospital Medical School)

Multiple polyposis of the colon in siblings was first described by Cripps (1882), and Doering (1907) first noted the frequency of malignant change in the condition. The condition is rare, since, although Stewart (quoted by Sawyer, 1940) found polypi in 4% of children, very few of these were multiple. Statements as to the frequency of malignant change vary. In Doering's original series there were 21 carcinomas in 40 cases of polyposis, Sawyer (1940) found malignant change in 40% of cases in a review of several series, while Friedell and Wakefield (1943) found only two carcinomas out of 19 cases. Many of the last series, however, were in children, and would not have been diagnosed without a special search. Genetically determined polyposis may not arise until middle life (Lockhart-Mummery, 1925), and seems to appear earlier in successive generations of the same family (Friedell and Wakefield, 1943). The earlier literature is reviewed by Dukes (1930).

Recently I have observed the following two cases of carcinoma of the rectum in young sisters. One had multiple polyposis of the colon and the other multiple telangiectases. Carcinoma of the rectum in siblings of this age is so rare that one must conclude that there is some connexion between the three conditions. The father of the sisters was killed in 1917, and they were his only children. Their mother is alive, and has three children by a second husband. The eldest of these is 25; all are well, and none have ever had any bowel troubles.

Case Histories

Case 1.—Edith was mentally defective, though she earned her living as a domestic servant. From the age of 4 she was cared for by nuns, who noticed nothing wrong with her bowels. Before this she is said to have had "tuberculous bowels," but her mother can give no grounds for this statement. At the age of 29 she was admitted to hospital with a very vague history of diarrhoea and passage of blood per rectum, was in *extremis*, and died a few days later. At necropsy the body was that of a poorly developed young woman, with foul teeth and many sebaceous cysts of the scalp. There was extensive bronchopneumonia, and a malignant ulcer at the pelvi-rectal junction with metastases in the para-aortic lymph nodes and in the liver. There were many polyps throughout the colon. The intervening mucosa appeared quite normal.

Case 2.—Maud, aged 32, was the sister of Edith. She presented herself at an antenatal clinic, pregnant for the first time, and gave no history of any upset of the bowels. However, a carcinoma of the rectum was discovered, and hysterectomy and colostomy were performed. She died seven months later. At necropsy a mass of growth filled the pelvis, and there were metastases in all the abdominal lymph nodes, the liver, and the peritoneum. Below the hepatic flexure the colon showed numerous minute bright-red telangiectases, each about 2 mm.

across, and separated from the next one by 2 cm. of normal mucosa. The rectum was buried completely in the mass of growth, and the exact origin of the tumour could not be determined.

Comment

From the last Census it appears that there were 3,353,100 women alive at that time between the ages of 25 and 35. In the same year 23 women in the same age group died of carcinoma of the rectum (Registrar-General's Annual Report, 1931). On any system of probability it is extremely unlikely that sisters will die of the same condition which has a death rate of only 2.3 out of a population of some 335,000. There would appear, therefore, to be statistical support for the contention that the conditions found in these women's colons were in some way connected and were also responsible for the development of their carcinomas.

I have to thank Mr. G. F. Stebbing and the Chief Medical Officer of the London County Council for permission to publish the second case, and for the kind invitation to perform the necropsy in Lambeth Hospital, where that patient died.

Medical Memoranda

Jejunal Diverticulosis Complicated by Haemorrhage

The following case may be considered unusual enough to merit publication.

CASE HISTORY

A man aged 73 was admitted to hospital on May 26, 1945, with a history of severe rectal haemorrhage for 24 hours. The onset was sudden and painless, the blood being dark at first but bright in colour later. He had had no previous attacks and had been in perfect health until three months previously, when he had developed pain in the upper abdomen two to three hours after meals, anorexia, flatulence, and slight loss of weight.

On admission he showed all the signs and symptoms associated with severe haemorrhage; the blood pressure was 80/50 and the haemoglobin 52%. A transfusion of 3 pints (1.7 l.) of blood was given. After passing several melana stools his condition settled down. The following investigations were carried out: (1) A test meal showed complete achlorhydria. (2) A barium meal revealed a hypotonic but otherwise normal stomach; the diverticula were not visible, but there was slight delay and partial obstruction in the upper jejunal coils. (3) A barium enema showed diverticulosis of the descending and the pelvic colon.

A laparotomy was performed on June 26. Eight diverticula were found in a segment of 14 in. (35.5 cm.) of the proximal jejunum, the first one being situated 4 in. (10 cm.) from the duodeno-jejunal flexure. The largest of these was 1½ in. (3.8 cm.) in diameter and contained a stony-hard and sharp concretion; the diverticulum stood out from the others and was discoloured, while the surrounding mesentery was congested. The rest of the intestinal tract was carefully examined and no further abnormality was found other than diverticulosis of the colon, seen in the skiagram. Resection of the affected loop with an end-to-end anastomosis was performed. A post-operative glucose-saline drip was set up and continuous gastric suction maintained for five days. The patient was discharged from the hospital on Aug. 8, and has been perfectly well since.

DISCUSSION

Diverticulosis of the jejunum is a relatively rare condition, though it is possible that many cases are overlooked, as they are often symptomless and may be difficult to demonstrate at necropsy. By insufflating the intestine *in situ* Rosedale and Lawrence (1936) found 4 cases in 300 consecutive necropsies. The diverticula are of the mucous-membrane-hernia type, similar to those found in the duodenum and colon. They may be single or multiple, as many as 400 having been present in a single case. The upper coils of the jejunum are affected most commonly, but the diverticula may extend on to the ileum. They occur along the mesenteric border where the main arteries pierce the muscular coats, and they push their way between the layers of the mesentery.

The first description appears to have been made in 1807 by Sir Astley Cooper, who found numerous pouches of the jejunum at a post-mortem examination on a man of 65. The aetiology

and incidence have been discussed in recent years by Butler (1933), Fraser (1933), Rosedale and Lawrence (1936), and Edwards (1939). Gerster (1938) reviewed the literature and found 187 published cases. Of these the majority were discovered accidentally at necropsy, during operations for other conditions, or during radiological examinations. Since then several more cases have been described by Edwards (1939) and Milnes Walker (1945). Flatulent dyspepsia and vague upper abdominal pain are among the symptoms present.

The complications of jejunal diverticula are as follows. (1) Acute diverticulitis, with or without perforation, abscess formation, or intestinal obstruction. This is the commonest complication, and 23 cases have been reported. (2) Acute intestinal obstruction due to concretion formation or volvulus (9 reported cases). (3) Traumatic rupture (1 reported case—Butler, 1937). (4) Haemorrhage: Guthrie and Hughes (1937), Tengwall (1931), and Braithwaite (1923) described cases in which haemorrhage was the leading symptom. In each instance the diagnosis was made at operation and recovery followed resection of the affected portion.

Small-bowel Obstruction due to Dried Fruit

In view of the cases of obstruction by dried fruit reported in the *Journal* last year, it was felt that a further case might be of interest. As in the case reported by Dorling (*B.M.J.*, 1945, 2, 426), the obstructing cause was a dried peach.

CASE RECORD

The patient, a woman aged 71, was admitted on April 22, 1945, complaining of abdominal pain and vomiting. Her history showed that she had been constipated for the 60 hours before admission. Her bowels had previously been regular. The vomiting had started 60 hours before admission, and had occurred six or seven times on the first day. The vomit was green in colour. In the 24 hours preceding admission she had vomited twice. The vomit was now brown. For 17 hours before admission attacks of abdominal pain occurred every five to ten minutes, and these were relieved by vomiting. The pain was localized to the umbilicus. Twenty years ago she had been advised to have a cholecystectomy, but had not undergone the operation. She had never been jaundiced, and had never had a similar attack before.

On admission her temperature was 98.4° F. (36.9° C.), pulse 100, respiration rate 20, and blood pressure 160/90. The tongue was dry and furred. Examination of the abdomen revealed no undue distension, visible peristalsis, or sign of a hernia. On palpation there was slight tenderness in the left iliac fossa, otherwise nothing abnormal was found. Intestinal sounds were not increased. Plain skiagrams in the supine position demonstrated gaseous distension of three loops of bowel in the left iliac region. In view of her poor general condition operation was deferred; an intravenous drip of glucose-saline was started, and gastric suction carried out through Ryle's tube. The pain had not recurred after she came into hospital. Twenty-four hours later she again complained of abdominal pain and her abdomen was more distended. Her general condition had, however, improved. Increased intestinal sounds were now associated with the colic, and were heard best in the left iliac region. In view of her past history, gall-stone obstruction was diagnosed.

At operation the abdomen was opened through a right paramedian incision, under a spinal analgesic—2 ml. of heavy percaïne. A small quantity of free fluid was present in the peritoneum, and a soft mass palpated in the left iliac fossa was found to be in the ileum, 2 ft. (30 cm.) from the ileo-caecal valve. The bowel above this mass, which was about 3 in. (7.6 cm.) by 1½ in. (3.2 cm.) in dimensions, was dilated, and, below, was collapsed. The mass was easily pushed up into the proximal dilated bowel and was removed through a longitudinal incision through the bowel wall. The bowel was closed in two layers transversely. The patient made a good recovery and was discharged on May 22, 1945.

On questioning her during convalescence she admitted that she had been preparing dried fruit five days before her admission and had nibbled at a dried peach. She was not very definite whether or not she had swallowed this, but the supposition was that, as she had only one tooth in her head, an upper incisor, this was indeed the case, since the mass itself, when opened out, very closely resembled the half of a peach.

My thanks are due to Mr. T. Meyrick Thomas, under whose care the patient was, for permission to publish this case.

Resident Surgical Officer, Miller General Hospital.

Reviews

ORTHOPAEDIC TREATMENT OF INFANTILE PARALYSIS

Traitement Orthopédique de la Paralyse Infantile. By M. Boppe. (Pp. 222; 118 figures. 170 francs.) Paris: Masson et Cie.

This work is said to be based upon the experience of ten years in observing, treating, and following up a large number of cases of infantile paralysis. As such it might be expected to be narrow in outlook—actually it does reflect admirably the views and methods of the great French school of orthopaedics. It is a pity that the literature of our two countries is not more readily available. Orthopaedics in general owes much to the great French pioneers, from Delpeche, André, Malgaigne, and Bonne down to the present day. It seems that in Britain we still have something to learn from our neighbours, but this book also suggests that our friends should be more familiar with our literature. The treatment of infantile paralysis should be based upon accurate recording of muscle loss. Anglo-American methods of recording muscular activity are apparently not used in France. A vast section of the field of orthopaedics is covered with characteristic French thoroughness. It illustrates one more that mastery of the orthopaedic problems of infantile paralysis provides a fundamental training for the would-be orthopaedist, including as it does questions of diagnosis; careful clinical examination of the locomotor system; the prevention of deformities, and the limitation of disability; the use of orthopaedic apparatus; operative surgery; rehabilitation in all phases, and resettlement of the disabled.

FOOD AND NUTRITION

Science and Nutrition. By A. L. Bacharach, M.A., F.R.I.C. Preface by Sir J. C. Drummond, F.R.S. (Pp. 142. 5s.) London: C. A. Watts and Co., Ltd.

The first edition of Mr. Bacharach's book was referred to at length in a leading article published in the *Journal* of Oct. 29, 1938, under the heading of "Food and Nutrition." We said then that it provided a refresher course in "classical nutritional science." In his second edition the author has done more than "repeat the mixture as before," because the book has been thoroughly revised and in parts rewritten. It is written in good strong English, and in these days, when problems of nutrition weigh so heavily upon us all, we can think of no surer guide to the practising doctor who wants to know the why and wherefore of diet constituents. Mr. Bacharach has the gift of thinking clearly and expressing his thoughts clearly. He takes the reader firmly along the path of exact knowledge, and gives him a real insight into the way the nutritional scientist tackles the matter of food and feeding. His sectional headings describe the scope of the book: "The Experimental Basis"; "Classical Nutritional Science"; "Minerals"; "Vitamins"; "Diet and Human Health." He has certainly succeeded in carrying out his object of steering "a very careful course between scientific inexactness on the one side and excessive detail on the other."

There are but a few points of criticism to make. His observation that "faeces are not really excreta at all—since they represent food that has not been digested at all or those parts of the food that have not" might be challenged. For example, faeces continue to be formed during starvation, and also form in a segment of bowel isolated from the rest of the intestinal tract. Although we may believe that partial deficiencies may be responsible for much "general ill-defined bad health," the evidence is not secure enough to justify the dogmatism implied in Mr. Bacharach's remarks.

In his last chapter, "The Necessity for the Optimal," he admits that he lays himself open to the charge of dogmatism. Few people would disagree with him that the optimum, and not the minimum, diet is the one to aim at for all, or that "a far greater improvement would result from securing that all who serve the community by working are so remunerated as to make adequate expenditure on food possible for all." But surely it is inaccurate to state that an optimum diet "is immeasurably beyond the reach of the average, or even the best paid, urban industrial worker..." (our italics). An

analysis of what the worker spends on food, tobacco, alcohol, and the cinema would give a measurement of the value the worker places on these items in the domestic budget.

Taken all in all Mr. Bacharach's book is astonishingly good value for the modest sum of five shillings, at which the publishers have priced it. We can think of no better handbook for that overworked man the general practitioner of medicine.

UROLOGY

The 1945 Year Book of Urology. By Oswald S. Lowrey, M.D., F.A.C.S. (Pp. 415; illustrated. \$3.00 or 18s.) Chicago: The Year Book Publishers; London: H. K. Lewis and Co.

The series of yearbooks emanating from Chicago is by now so well known that no general description of the latest one is necessary. That volume which deals with urology will be particularly useful to those who, because of war service, have been out of touch with their specialty and are anxious to discover what advances have been made in it during their absence. But the method of classification adopted by the editor does not make this as easy as it might have been. If any criticism is to be made of an otherwise excellent work it is that greater prominence should have been given to the more important advances in diagnosis and treatment. This would have allowed the reader to discover at a glance what was of vital importance to him and what was merely of interest. For example, instead of being dispersed throughout the text, unusual cases and rare complications could have been brought together in a separate chapter. It would also have been valuable if the chief lines along which urology had advanced could have been indicated in a preface. In spite of the war progress has been made, for example, in the treatment of carcinoma of the prostate and in the use of penicillin in combating certain urinary infections. Apart from the criticism made about the method of presenting the material, the 1945 volume of the *Year Book of Urology* is as valuable and as well produced as its predecessors.

ANIMAL PHYSIOLOGY

Physiology of Farm Animals. By F. H. A. Marshall, Sc.D., LL.D., F.R.S., and E. T. Hahn, M.A. Third edition. (Pp. 339; 119 illustrations. 18s.) Cambridge: University Press, 1945.

Part of this book reflects Dr. Marshall's eminence in the study of reproduction (67 pages) and Mr. Hahn's accomplishments in nutrition and growth (53 pages). But the 205 pages of systematic physiology do not fulfil the expectations of those who read in the preface that "the book is specially intended for students of agriculture who wish to obtain some knowledge of the processes of physiology as they occur in the domestic animals." Processes as they occur in *man* are too frequently described—an unnecessary lapse for anyone who is conversant with the literature of veterinary physiology of the past 85 years. The text reflects an unawareness of what animals do and how they do it; we listed 32 factual errors. For instance, the tuberculin test is incorrectly described (p. 144). The grazing horse does not "bite off the grass with its incisor teeth" (p. 48); with its incisor teeth the horse grips the grass and then by a jerk of its head it tears off the grass. The temperature of the normal fowl in Great Britain is not 101-6° F. (p. 142); it is 104.5° F. We are not aware that "horses whose legs become swollen or oedematous through much standing may often be cured by moderate exercise" (p. 104); can the swelling be due to the authors' belief that "the cartilage [articular] is covered by the 'synovial membrane' (p. 173)? The statement that "salts taken in excess of the physiological optimum are . . . rapidly excreted" (p. 305) is at variance with current notions of toxicology—e.g., NaCl poisoning. The text is sprinkled with nebulous negatives—e.g., "the pig is not purely herbivorous" (p. 58); "sugar is rarely or never present in horse's urine" (p. 134); "crude fibre is but poorly digested by the bird" (p. 80).

Students desiring reliable information on the physiology of the domestic animals should read the late Sir Frederick Smith's *Manual of Veterinary Physiology*, first edition 1892, fifth edition 1920. Smith blended an extensive experience of animals and their behaviour with systematic physiology; also he acknowledged the work of his eminent predecessors as far back as Prof. Colin of Paris, "the father of veterinary physiology," and those distinguished pioneers in animal nutrition, Sir John Lawes and Sir Joseph Gilbert of the Rothamsted Experimental Station.

RACIAL DIFFERENCES

Man's Most Dangerous Myth: The Fallacy of Race. By M. F. Ashley Montagu. With foreword by Aldous Huxley. Second edition, revised and enlarged. (Pp. 304; \$3.25 or 22s.) New York: Columbia University Press; London: Oxford University Press, 1945.

The speculations, the beliefs, and the practical deductions of race theorists have, to put it mildly, suffered something of a set-back in recent years. We have, moreover, been fortunate in this country, as compared with most, in that problems of racial differences have troubled us relatively little. This book, a second amplified edition, comes from the United States, where the colour issue bulks large in practical politics, and Semitism or anti-Semitism are far from unimportant even though seldom emerging into public discussion. It seems to have been written at white-heat and the effect is curiously exhausting; there is too much banging at open doors, too much tilting at windmills, too much struggling up icy slopes with banners bearing a strange device.

The general theses of the book are in the main sound enough, or at the least much sounder than the race-theories Dr. Ashley Montagu sets out to attack. A more temperate refutation of unsound opinions, the avoidance of confusing repetition, and a clear exposition of present-day scientific findings and views might have produced a good book. Those who are already converted, and who hold strong emotional views on the subject, will be delighted with Dr. Montagu's polemical presentation. Others of similar type of mind may become converted. Those of more judicial temperament will wonder whether one flat assertion is more convincing than another—whether, for example, the bald statement "The mule combines most of the good qualities of its parental stocks" is more convincing at sight than would be its converse. They will wonder whether some of the scientific men the author castigates can really have been such fools and whether their opinions can have been quoted quite fairly. Dr. Ashley Montagu had a good case but has unfortunately gone a long way towards spoiling it.

Notes on Books

In *Penicillin: A Dramatic Story*, Dr. Boris Sokoloff is, needless to say, writing for the general public. His style may be deduced from the title: in general his account is correct, though marred by some inaccuracies, such as the completely imaginary definition of the unit of penicillin on p. 26. American sources have provided most of his information, and part of the story of early developments in the U.S.A. may be new even to informed English readers. The book is published at 7s. 6d. by George Allen and Unwin.

The most recently issued Bulletin (No. 5, 1945) of the Department of Labour and National Service of Australia is entitled *Amenities in War-time Factories*. It gives brief information about the arrangements that have been found to be the most satisfactory in leading Australian factories, both large and small. It discusses lockers and change rooms, washing facilities for hands and feet, and the provision of showers for workers employed in arduous and dirty work. The equipment of first-aid rooms is given in some detail, as is that of mess rooms. Ventilation and lighting are briefly discussed, and the whole of the Bulletin is very well illustrated. In the words of the introduction to the pamphlet, "All this represents a considerable forward step from the days of dark and dingy factories when employees had no rights and no amenities."

The Official Medical Register for 1946 has been published on behalf of the General Medical Council by Constable and Co. (Orange Street, W.C.2) at 21s., post free 22s. The table printed in the introductory section shows that 2,666 names were added last year. New registrations numbered 1,268 in England, 581 in Scotland, 428 in Ireland, 124 on the Colonial Register, and 265 on the Foreign Register. The total number of names on the Register at the end of last year was 75,133, being 1,457 more than on Dec. 31, 1944. The total number at the end of 1935 was 58,361, and at the end of 1925 it was 51,738.

The National Physical Laboratory has published a pamphlet *Tests on Volumetric Glassware*, prepared by its Metrology Division. The regulations governing Class A tests are designed to meet the requirements of apparatus intended to possess the highest accuracy. The Class B regulations are intended to set a standard for vessels of good commercial quality, satisfactory for general use. The pamphlet gives a list of verification fees and other charges, and notes on procedure. Any reader who wishes for a copy can receive one on application to the director, National Physical Laboratory, Teddington, Middlesex.

SATURDAY MAY 4 1946

PAUSE FOR DEBATE

We go to press this week in the middle of two of the most important discussions since 1911 affecting the future of medicine. Full reports of the Special Representative Meeting and of the Second Reading debate on the National Health Service Bill will appear in next week's *Journal*. The substance of the speech of the Minister of Health, opening the Second Reading of the National Health Service Bill on Tuesday, is reported elsewhere in this issue.

In order to fix discussion on the main issues, the Agenda Committee for the Special Representative Meeting on May 1 started certain resolutions submitted by Divisions. A summary of these will show the general direction of the debate. An amendment by Preston is in favour of the proposed form of local administration for general practitioners and regional administration for hospitals, whereas Liverpool advocates the principle of regional organization for all health services. Another pair of opposite amendments refers to the ownership of hospitals. Oxfordshire adopts the disputed resolution of the Consultant Services Committee in favour of State ownership of hospitals provided that the constitution of the regional boards is acceptable to the profession; Marylebone, however, views with disfavour the proposed transfer of hospitals and "the consequent destruction of local interest in hospital services, and the confiscation of trust funds intended by donors for specific purposes." On the question of buying and selling practices Hastings approves of the proposed abolition of this custom provided adequate compensation is paid in respect of loss of capital values. This is supported by Leeds, in the form of not being opposed to the Government's proposal provided "terms of service and remuneration satisfactory to the profession be first agreed." Bradford, on the other hand, "regards as elementary the right to sell and buy practices as at present." Paddington considers that the measures proposed in the Bill for the distribution of doctors are reasonable, but West Suffolk amends "that there shall be no control over doctors in regard to the choice of area in which they shall practise." Payment by an adequate capitation fee, without a fixed part-salary and without restrictions, is recommended by Newcastle-upon-Tyne and Tyneside; remuneration of general practitioners by basic salary plus capitation fees—both of which must be acceptable to the profession—is advocated by Oxfordshire.

On the general attitude to the Bill and the Act to come, Harrow, Guildford, and Rugby urge that a plebiscite or a referendum to the whole profession should be taken,

either forthwith or later. Guildford and Rugby move that a referendum should be taken immediately, before the passage of the Bill into law. Harrow moves "that before the Council recommends practitioners to accept or to refuse service under the Act, a plebiscite of the whole profession should be taken in a form to be approved at open meetings of the profession." Division of opinion on the Bill as a whole is represented in the motions by City on the one hand, and by Goole and Selby and by Gateshead on the other. City "regards the National Health Service Bill as an important step towards the provision of a comprehensive service available to the whole community, and therefore approves its general framework." The rejection of the proposed enactments of the National Health Service Bill in their entirety is moved by Goole and Selby. Between these two extremes, Gateshead disapproves of the methods proposed in the Health Bill to achieve the agreed ends of improving and co-ordinating the existing medical services. Criticism of the Minister for not entering into a discussion of principles and details with the Negotiating Committee before the Second Reading of the National Health Service Bill is voiced by Kingston-on-Thames. The outcome of the debate on these resolutions will in considerable measure define the attitude of the majority of doctors to the present Bill and will afford a useful pointer to the probable reactions of the medical profession to the Act under which it will be expected to serve.

Criticism of various aspects of the Bill comes from another quarter in the form of comments made by Mr. Frank Byers, M.P., on behalf of the Liberal Parliamentary Party, which welcomes the proposal to set up a health service which will be available to all, irrespective of their means. It is denied, however, that the Bill justifies its claim to establish a comprehensive service. Liberals would have favoured "a true comprehensive charter of health dealing with the three matters concerning health—namely, (a) the prevention of disease, (b) the maintenance of health, and (c) the cure of disease." The present Bill, it is stated, deals only with the third of these. The principal criticism of the Liberals is that far too much is left to regulation, with the result that the Minister can make drastic changes in the service and modify initial arrangements. This deprives Parliament of adequate control over the development of the health service and of adequate supervision of the actual provisions of the Bill. The democratic principle of the Liberal report has been largely abandoned in the Bill, in that the Minister appoints the Committees, which are not to be elected by either professional bodies or the public. The Liberals consider that both voluntary and municipal hospitals should have their basic needs met from State funds, but should be allowed to raise money locally for the provision of special amenities and for research and experiment. "Local enthusiasm should be encouraged to express itself in this way by gift and endowment for special amenities and facilities over and above the general standard." We should take warning from the Liberal view that there is no adequate safeguard in the Bill for the medical profession: "If the major part of their remuneration is to be by salary rather than by capitation fee there is a serious danger of the doctor being

reduced to the rank of a salaried civil servant." The Liberal Party also considers that there is insufficient safeguard for the rights of the public to make complaints concerning hospital treatment; to remedy this it suggests the appointment of special public relations officers to the regional hospital boards and hospital management committees, "not only to publicize the work of the hospitals but to provide a channel through which the boards and committees may be directly approached by members of the public in order to have their grievances ventilated and rectified." The omission of the industrial medical service from the scheme is criticized as "a most retrogressive factor which tends to label the Bill as a purely curative instead of preventive measure." A further criticism is that inadequate attention in the Bill is given to the profession of nursing, midwifery, and domestic service.

In his speech before a crowded House of Commons on Tuesday Mr. Aneurin Bevan showed himself to be insensitive to the many criticisms levelled at the major issues raised by the Bill. He defended the proposed transfer of all hospitals to State ownership as the only method of securing a co-ordinated and planned hospital service. He left unchanged the powers of direction of the Medical Practices Committee, and the proposal to pay general practitioners part by salary and part by capitation fee. He resisted the suggestion that has come from many quarters that the administration of all treatment services should be at the regional level. His observations on these and other features of the Bill will be found at page 690. The debate continues.

THE HERITAGE OF DISABLEMENT

The League of Nations is being wound up, but one part at least of the Treaty of Versailles continues to operate vigorously. This is the part under which the International Labour Office was created in 1919, and although the headquarters of that body now look out upon the St. Lawrence instead of upon Lake Geneva it is promoting international collaboration in the field of industry as effectively as a disjointed world will allow. If what it puts out is often incomplete and late in arrival, that is due to the tardiness of national Governments and their employers' and employees' organizations. One of its latest pieces of work, assembled in six months—which is quick time for any international document—is a preliminary report of 300 pages on the training and employment of disabled persons.¹ The survey was planned on comprehensive lines: to assess the extent of this problem in different countries, the administrative organization so far as any has been set up, the procedures for medical and vocational rehabilitation and the co-ordination of the two, and for training, retraining, and sheltered employment. It is disappointing that so few countries are making a contribution. Almost all the information comes from Great Britain and the Dominions, Soviet Russia, and Scandinavia, one or two small countries in Western Europe, and the United States and a few South American republics; yet in some of the countries not

recorded there must be an enormous mass of war disablement not only unprovided for but even unassessed. It is true that there is an appendix giving an account of the highly efficient scheme for the rehabilitation of disabled soldiers in Nazi Germany. It was set up in 1940, and in 1944 it was reported that only 15% of all war-disabled men had to be trained for an occupation different from their former one; more than 60% were able to return to their old places, and 15% were trainable for higher posts. All that, however, is of historical interest only, and what the conditions are now in the ex-enemy and liberated countries of Europe this survey does not tell us.

Even from the countries which do furnish reports on the subject no very clear picture emerges. No country seems to have more than fragmentary statistics, though enough has been collected to show that the problem is formidable. A legislative committee in the United States has found that the physically impaired "constitute an enormous segment of our population." Everything depends, of course, on where the line is drawn. As yet there is no clear identification of the disabled. If the term is used in its widest sense it may be held to cover a very large proportion of all citizens. Sweden, with a population of some seven millions, lists no fewer than 480,000 disabled persons, and these include "punished" persons, meaning those who have served a prison sentence, also the alcoholic, the so-called over-age, the nervous, and the hard of hearing. On the other hand, Australia limits its classification to those who have been injured either in the Forces or in other services of the Commonwealth. Some countries object to the term "disabled" altogether because it implies a separate classification which it is alike impossible and undesirable to delineate in practice.

What, after all, is a disability? It does not necessarily imply vocational handicap, and vocational handicap may be brought about by a disability which cannot be defined or measured. Some disabilities may prevent employment in certain occupations, but may even be an advantage in others. A report by the U.S. Civil Service Commission states that workers with limited or no hearing are preferred by many employers for noisy jobs, such as those of boilermaker, riveter, and welder. Persons of tiny stature have been found extremely useful in aircraft plants, to do the final riveting in the tight corners of wings and fuselages. We have heard of a luxury hotel which bars pageboys who wear glasses, but welcomes, if not insists upon, spectacled receptionists. A minor disability in some circumstances may mean a far greater handicap to employment than a severe one. The same type of disability may mean a serious handicap for one person but not for another, owing to differences in personal qualities, skills, or interests; and it needs the wisdom of Solomon and the patience of Job to decide how much inefficiency in a given case is due to a physical disability and how much to lack of character or "guts." The worst kind of case is found in the man who, to quote an American employment commissioner, "has had time to kid himself that he is unemployable."

In this country the history of rehabilitation, apart from some isolated, though excellent, efforts, may be said to go back for no more than five years. It began in the Services—in the R.A.F. even before the Battle of Britain—and it

¹ International Labour Office. *Studies and Reports: Series E (The Disabled)*, No. 7. Montreal, 1945. (\$1.50. or 6s.)

has been slow to come into civil life. But ideas on the subject are clarifying, and we now conceive rehabilitation as beginning immediately after the accident or whatever caused the disability and continuing until the man is again on the pay-roll. It includes good surgery, convalescent care, remedial and other exercises, bringing in all that is meant by positive health, and going on to resettlement, with vocational guidance, job analysis, training or retraining, placement, and social medicine. Under the Disabled Persons (Employment) Act, 1944, routine employment for the disabled becomes a matter of right instead of charity. In this country we have—what they lack in many countries—the administrative responsibilities entrusted to one Government Department, the Ministry of Labour, instead of being spread over a number of agencies. The whole subject has been closely studied by a special committee of the British Medical Association, whose findings will be published in the near future.

A difficulty in several countries, brought out in the survey by the International Labour Office, is the unwillingness to make medical reports a matter of routine for persons applying for help in obtaining suitable employment. Many disabled persons feel, naturally enough, that medical reports will emphasize what they cannot do rather than what they can do, and so they may be stigmatized and placed in a permanent category of unfitness. In Great Britain the confidential medical report provides the basis of the rehabilitation officer's action; but it is not compulsory, and it is open to the man to ask instead for an independent medical examination. In the United States, though medical reports are not compulsory by law, they are so in fact, because they are an essential preliminary condition of eligibility for rehabilitation. Medical follow-up work is carried out in Great Britain, where it is the responsibility of the medical authorities, but it is the exception rather than the rule elsewhere. Hospital or convalescent-centre interviewing seems to be winning general favour, and is said to be extended widely in the Soviet Union, where also special conditioning centres are part of the organization for the disabled, as they are in British countries and in the United States. The most cheerful part of this preliminary survey is a chapter which brings together a very large number of instances of work actually undertaken by the disabled. There seems to be no type of deformity or mutilation which, after careful treatment and adjustment, cannot be matched with some type of job—clerical, mechanical, skilled-trade, technical, scientific, or professional. The United States Civil Service Commission, already quoted, states that workers with deformities of the spine are being successfully employed in a wide variety of work in which no heavy lifting is required, that persons with arrested tuberculosis are working well in any number of positions calling for light, moderate, and semi-arduous duties, provided the environment is favourable (for example, free from fumes and dust), and that organic heart cases suitably compensated often excel in positions involving desk or bench duty and in machine-shop and drafting work. As experience is gained and as more countries are able to follow a constructive rehabilitation programme the I.L.O. hopes to report adequately. At present few countries can make any claim even to com-

pleteness in outline, let alone detail. The organization of sheltered employments is still in the early stage of development, though the significant thing is the general acceptance of the need for such provision. The same is true of placement arrangements: a few years ago such things were unknown, but now a number of countries are establishing placement machinery designed to work in a manner both scientific and humane. In Great Britain the employment exchange network has been reinforced by the setting up of a national advisory council and local committees which include representatives of employers and workers as well as others with experience of placement work. Finally it is well to be reminded that even the most complete and satisfactory plans for rehabilitation wait upon the maintenance of a high and stable level of employment.

EXAMINATION OF THE TONGUE

The tongue ranks with the pulse and the temperature as one of the primary objects of attention in the examination of patients, but according to Frantzell and co-workers¹ no systematic study of the gross aspect of the tongue appears to have been made with the aid of a detailed photographic analysis. They base their own report on the clinical and photographic examination of some 1,500 tongues.

The most important variations from the normal are the dry, the coated, and the smooth tongue. Loss of body fluids produces a dry tongue, and perhaps the greatest value of routine inspection of the tongue is the evidence it may present of dehydration. The coated tongue is chiefly due to overgrowth of the filiform papillae, which are normally worn short by mastication. Enlargement of the fungiform papillae gives rise to the strawberry tongue which is characteristic of scarlet fever; the cause of the enlargement is not known, but it may be oedema of the lingual papillae. A smooth tongue is due to atrophy of the papillae; it was the commonest abnormality in Frantzell's group of cases. It is found characteristically in idiopathic hypochromic anaemia and pernicious anaemia, but it is also common in thyrotoxicosis, cardiac decompensation, and after pneumonia. There seems to be no causal connexion between a smooth tongue and the wearing of false teeth, though naturally the two conditions are often found together. The smooth tongue of hypochromic anaemia regenerates rapidly on treatment with iron, so rapidly in fact that it is probable that we are not dealing with an improvement caused by increased haemoglobin values. It is easier to assume a peripheral action of the iron on the tissues. The same is true of the response to liver therapy in pernicious anaemia. The common factor in these various causes of smooth tongue is probably a disturbance in the oxidative processes of the cells of the papillae. Iron enters into the composition of a number of the respiratory ferments, and the same is true of riboflavin and nicotinic acid. The cells therefore atrophy when they are starved of iron or these two vitamins. Heart failure produces anoxaemia; acute infection depresses the serum iron, and hyperthyroidism increases the metabolic demands of the cells. Thus the tongue may be regarded as an indicator of both the hydration and the oxygenation of the tissues. The precise mode of action of the anti-pernicious anaemia factor can as yet hardly be guessed, though it is suggested that it may stimulate the proliferation of the epithelial cells, as it does those of the bone-marrow.

¹ Frantzell, A., Tornquist, R., and Waldenström, J., *Acta med. scand.*, 1945, Fasc. III, 122, 207.

The scrotal tongue does not appear to have much significance. Frantzell believes this condition can be subdivided into two groups—the deeply furrowed tongue or *lingua plicata*, and the mamillated tongue. *Lingua plicata* is found in normal individuals. A mamillated or hummocky appearance of the tongue is often seen after regeneration of an atrophic mucosa. A smooth tongue often goes with an atrophic gastric mucosa, and it is possible that a mamillated tongue may accompany the *état mamelonné* which gastroscopists have described in the stomach.

CONSTRICTIVE PERICARDITIS

The cardinal clinical features of constrictive pericarditis—certain of which were described in England by Richard Lower¹ in 1669, more than two centuries before the work of Pick,² whose name is so often applied to it—are well established—dilated pulsating veins, oedema, ascites, liver enlargement, immobility of the heart, and dyspnoea. But the morbid physiology of the circulation which produces these has only lately been clarified by Blalock and Burwell,³ Heuer and Stewart,⁴ and Hitzig.⁵ The most important effect of the constriction of the heart by its cuirasse of thickened and sometimes calcified pericardium is a limitation of diastole; the capacity of the pump is reduced, and its delivery is consequently restricted. The cardiac output per beat and per minute is lessened, the circulation rate slows, the systolic and pulse pressures fall, and the heart can respond to exercise only by acceleration. These alterations in the arterial circulation induce a progressive "inflow stasis" on the venous side; the veins dilate and may pulsate, and the venous pressure rises. The main brunt of the venous stasis falls upon the liver, perhaps because basal cardiac adhesions hold wide open the orifices of the valveless hepatic veins.

The radiographic signs of constrictive pericarditis may be misleading unless films are supplemented by screening (Sellors⁶) and by tomography (Meier⁷). In general the heart shadow is small with broadening in its upper part from distension of the superior vena cava and innominate veins; pulsation is diminished, and there is a reduced excursion of the aortic arch, ascension of the heart with deglutition, and, sometimes, calcification in sheets, plaques, or bands. Calcification may, however, mimic or be mimicked by calcification in a myocardial infarct, in an aneurysm, in a mural thrombus, in a coronary artery, or in annular fibrosis round the mitral orifice (Hohenner⁸); it should be remembered that constriction may occur without calcification, and calcification without constriction (Sellors). Even the reduction of the size of the heart, once regarded as a cardinal sign, is not invariably obvious, for it may be obscured by the shadow of a greatly thickened pericardium (Sellors). The only certain radiological feature is a diminished excursion of pulsation which may be quite localized, and must be sought by screening all available aspects of the heart outline.

The surgical treatment of constrictive pericarditis has become progressively safer since Heuer and Stewart⁴ in 1939 reported an immediate operative fatality rate of 33%, and a later fatality rate of 10% in 143 collected cases. T. Holmes Sellors⁶ has now reported 5 cases with 1 post-operative death. Against this mortality it may be argued that without operation the disease may be compatible with long and active survival—Nils Finsen⁹ suffered

from it for 21 years and won a Nobel prize. Yet in general it produces a crippling disablement if untreated. Sellors employs a transpleural approach through the fourth left interspace. He removes both parietal and visceral pleura, starting his dissection over the right ventricle, but proceeding quickly to free the left ventricle also, to avoid sudden engorgement of the lungs. Cardiac arrest (preceded usually by warning extrasystoles) and haemorrhage (from opening of the heart cavity) are the main immediate dangers, and there is some risk of cardiac dilatation and ventricular fibrillation later.

After operation, though the pulse pressure rises to normal almost at once, the venous circulation responds more slowly, but amelioration of symptoms is usually greatly out of proportion to the improvement in signs. Irregularities of rhythm present before operation usually persist after it, but irregularities which arise during operation are generally transitory. In all four of Sellors's successful cases the patient recovered full capacity for exercise, though one developed a cold abscess in the thigh 3½ years after pericardiectomy. The possibility of operative intervention reawakening a latent tuberculous process cannot be entirely disregarded, for there is reason to believe that constrictive pericarditis is of tuberculous origin more often than was formerly supposed (White,¹⁰ and Blalock and Burwell³). Sellors indeed regards tuberculosis as the most important cause of constrictive pericarditis.

MEDICAL ABSTRACTING SERVICE

At its meeting on April 3, 1946, the Council of the B.M.A. accepted the recommendation of the Journal Committee that a medical abstracting service should be set up in the Editorial Department of the *British Medical Journal* under the general direction of the Editor.

The staff for this service has yet to be appointed, and the conditions of appointment are described in the advertisement columns of this week's *Journal*. The service will be the direct responsibility of a medical Editor of Abstracts and a medical Assistant Editor. The appointments will be on a whole-time basis, and we would draw the attention of medical men interested in this kind of work to the terms of the advertisement. It is hoped that work on the project will begin in July of this year, so as to make it possible to publish the first two issues of the proposed new abstracting journals in January, 1947. The aim is to provide a comprehensive abstracting service of the world's medical literature in the form of one monthly journal devoted to medicine, and a second to surgery, gynaecology, and obstetrics. These two monthly journals will be much on the same lines as the *Bulletin of War Medicine*, which ceases publication in August of this year. In addition, it is proposed to supply special abstracting sections to the Editors of the quarterly journals published by the Association, and a general section weekly to the *British Medical Journal*—a continuation in a modified form of the Key to Current Medical Literature which had to be discontinued when war broke out in September, 1939. We take this opportunity of drawing attention also to another advertisement, for a medical subeditor for the *Journal*.

On April 25 Dr. T. F. Fox, Editor of the *Lancet*, was elected a Fellow of the Royal College of Physicians of London under the by-law relating to persons not Members of the College who have distinguished themselves in any branch of the science or practice of medicine and who have been nominated by the Council as specially eligible.

THE MINISTER'S SPEECH

HEALTH SERVICE BILL

Mr. ANEURIN BEVAN moved the Second Reading of the National Health Service Bill in the House of Commons on April 30. The Minister said that in the last two years there had been such a clamour from sectional interests in the field of national health that they were in danger of forgetting why the proposal of a National Health Service was brought forward at all. The scheme which anyone must draw up dealing with National Health must necessarily be conditioned and limited by the evils it was intended to remedy. The first reason why a health scheme was necessary at all was because it had been the firm conclusion of all parties that money ought not to be permitted to stand in the way of obtaining an efficient health service. Although it was true that the National Health Insurance system provided a general practitioner service and drugs for something like twenty-one millions of people, the rest of the population had to pay whenever they desired the services of a doctor.

The Minister continued: "It is cardinal to a proper health organization that a person ought not to be financially deterred from seeking medical assistance at the earliest possible stage. It is one of the evils of having to buy medical advice that in addition to the natural anxiety that arises because people dislike hearing unpleasant things about themselves—and tend to postpone consultation as long as possible—there is the anxiety of having to pay doctors' bills. Therefore, the first evil we must deal with is that the whole thing is the wrong way round."

The National Health Insurance scheme did not provide for the self-employed and for family dependants. It depended on insurance qualifications, and, no matter how ill you were, if you ceased to be insured you ceased to have free doctors. It gave no backing to the doctor in the form of specialist services. The doctor had to provide himself, out of his own discretion and personal connexions, hospitals and specialists for his patients. In the overwhelming number of cases the services of specialists were not available to poor people.

Scope and Availability.—"Our hospital organization has grown up with no plan and no system. It is unevenly distributed over the country. It is, indeed, one of the tragedies of the situation that very often the best hospital facilities are available where they are least needed. In the older industrial districts hospital facilities are inadequate. Many hospitals are too small. There are about 70% with fewer than 100 beds and over 30% with fewer than 30 beds.

"No one can possibly pretend that such small hospitals can provide general hospital facilities. There is a tendency in some quarters to defend the very small hospital on the grounds of its 'localism,' and its intimacy, and other rather imponderable reasons of that sort. But everybody knows that if a hospital is to be efficient it must provide for a number of specialized services. Although I am not a devotee of bigness for the sake of bigness, I would rather be kept alive in the efficient, cold altruism of a large hospital than expire in a gush of warm sympathy in a small one."

Mr. Bevan went on to say that the condition of the teeth of the people of Great Britain was a national reproach. As a consequence of dental treatment having to be bought it had not been demanded on a sufficient scale to stimulate the creation of sufficient dentists, and there was a woeful shortage of dentists at the present time. About 25% of the people could obtain their spectacles and have their eyes tested by means of the assistance given by approved societies, but the general mass of the population had no such facilities.

"One of the evils from which this country suffers is that sufficient attention has not been given to deafness and that hardly any attention has been given so far to the provision of cheap hearing aids and their proper maintenance. I hope to be able to make very shortly a welcome announcement on this question."

Another disability from which our health system suffered, in the Minister's view, was the isolation of mental health from the rest of the health services. The present Bill did not alter the Lunacy Acts, but they would have to come to that later on. The present Bill did for the first time bring mental health

into the general health scheme. It should be one of the objects of any civilized health service to enable any person who felt mental distress to go to a general hospital for advice so that the condition might not develop into a more serious stage.

"This Bill provides a universal health service without any insurance qualification of any sort whatsoever, available to the whole population freely. It will universalize the best of advice and treatment." There would be some limitations for a while because they were short of many things. They were short of dentists, nurses, and of hospital accommodation. It would be some time before the Bill could "fructify fully in effective universal service."

Specialists would be available not only at institutions but for domiciliary visits when needed. The practical difficulties of carrying out these services were very great, but "when I approached this problem I made up my mind that I was not going to permit any sectional or vested interests to stand in the way of providing this very valuable service for the British people."

Voluntary Hospitals.—The voluntary hospitals had done invaluable work. When hospitals could not be provided by any other means they came along and they had a long history of devotion and self-sacrifice behind them. But they had been established often by the caprice of private charity. They bore no relation to each other. Two hospitals close together often tried to provide the same specialist services unnecessarily, while other areas had not that kind of service at all. They were badly distributed. To leave the voluntary hospitals as independent units was impracticable. "Furthermore I believe it is repugnant to the interests of the community that hospitals should have to rely on private charity. I have always felt a shudder of repulsion when I have seen nurses and sisters—who ought to have been at their work—going about the streets collecting money. We must leave that system behind entirely. The implications of doing this were very considerable," said the Minister. "I have been forming some estimates of what might happen to voluntary hospitals and finance when the all-in Insurance Act is passed. The estimates show that between 80% and 90% of the revenue of the voluntary hospitals will be provided by public money. In many parts of the country it is a travesty of the facts to call them voluntary hospitals. In the mining and textile areas the industrial population pay a weekly contribution for the maintenance of their voluntary hospitals."

"When I was a miner I used to attend meetings at which votes of thanks were passed to the managing director of the colliery for his generosity to the hospitals. But when I looked at the balance sheets I found that 97½% of the money was provided by the miners." It was a misuse of the term "voluntary" to call the voluntary hospitals "voluntary." For these and other reasons he had decided that the voluntary hospitals must be taken over. He knew the decision would cause a considerable amount of resentment. "I am not concerned with the voluntary hospitals," he added, "I am concerned with the people they serve."

The appropriate hospital unit was one of about 1,000 beds—not in the same building. Specialist services could only be provided with a grouping of that size, and this could not be brought about if the hospitals remained separate autonomous bodies. The main hospitals must have feeders. Cottage hospitals had striven to give services which they were not equipped to give. They strove to reach a status they never could reach and the welfare of the patients was sacrificed to the ambitions of the institution. Voluntary hospitals, to be grouped properly, must submit themselves to proper organization, and that was impracticable so long as they remained under separate management.

On the other hand, many local authorities had never exercised their hospital powers. Some were too poor. Some were too small. They had inherited their hospital system from the Poor Law. Though some of the local authorities' hospitals were among the best in the country others were a cross between a workhouse and a barracks. As a gathering ground for patients the local authorities were no more effective than the voluntary hospitals.

It was quite impossible to hand over the voluntary hospitals to local authorities. It would mean that once more they would be faced with all kinds of anomalies. Local authorities were too small and without the financial capacity to be effective

hospital units Tuberculosis sanatoria, isolation hospitals, infirmaries of all kinds, and hospitals of every kind were all necessary in a general hospital service "I decided that the only thing to do was to create an entirely new hospital service to take over voluntary hospitals and local government hospitals and organize them as a single hospital service throughout the country. If we are to carry out our plans and provide all the people of Great Britain with the same service, then the nation will have to carry the expense and not put it upon the shoulders of any authority."

A number of investigations had been made from time to time into the subject, and the conclusion always reached was that an effective hospital unit should be associated with a medical school. By grouping hospitals around medical schools it would be possible to provide what was very badly wanted—the means by which general practitioners could be kept in more intimate association with new medical thought.

One of the shortcomings of the existing service was the isolation of the general practitioner, "who practised in loneliness and had no access to new medical knowledge." By associating the general practitioner with the medical schools through a regional hospital organization it would be possible to refresh and replenish his knowledge. The regional hospital organization was the authority with which specialist services were to be associated.

"It is not intended," he said, "that the Regional Board should be a conference of persons representing different interests and organizations. It is intended that they should be drawn from persons of the profession, from the major public health authorities in the areas, from medical schools and from those with long experience in voluntary hospital administration. By leaving ourselves open to take the best sort of individuals on these hospital boards, we hope before long to build up a high tradition of hospital administration on these boards themselves."

Any system which made the boards conferences, any proposals which made the representatives delegates would at once throw the hospital administration into chaos. Although he was prepared to discuss the constitution of the boards, he hoped he would not be pressed to make them "merely representatives of different interests."

General Practitioner Service.—"The proposal which I have made," he continued, "is that general practitioners shall not be in direct contract with the Ministry of Health but in contract with new bodies." Mr Bevan emphasized that his proposals did not put the doctor under the local authority, they merely engaged him on contract with an entirely new body the local Medical Executive, on which dentists, doctors, and chemists would have "half representation." The whole scheme would provide a greater degree of medical representation than ever before. It would, moreover, strengthen democracy by giving doctors full participation in the administration of their own profession.

Doctors, however, would not become civil servants. The scheme did not create one additional civil servant. Indeed, by taking the hospitals away from the local authorities very many people would be "enfranchised." There would not be any "huge bureaucracy," and the doctors would not be the "slaves of the Minister of Health."

Referring to the uneven distribution of doctors, he said that in South Shields before the war there were 4,100 persons to one doctor. In Bath there were 1,590. Dartford had 3,000, compared with Bromley's 1,620. Swindon had 3,100, but Hastings had 1,200. "That distribution is most hurtful to the health of our people. It is entirely unfair, and, therefore, if the health services are to be carried out there must be brought about a redistribution of general practitioners throughout the country."

If the country was going to get the doctors where they were most needed it could not possibly allow a new doctor to go to any particular area, merely because he had bought the practice. Proper distribution of doctors would automatically kill the sale and purchase of practices. "I have always regarded the sale and purchase of medical practices as an evil in itself. It is tantamount to the sale and purchase of patients."

Every time certain doctors argued for a high compensation for the loss of the value of practices it was an argument

against the "free choice" they claimed in the matter. Mr Bevan admitted that there would be very great hardship if doctors received no compensation for the purchase of those practices whose value might be affected. That course would be most unjust, but when the Government proposed to grant £66,000,000 for compensation the doctors were being treated very generously. He added that the profession would be advised about the equitable distribution of these funds among the claimants.

Some Kind of Hedonism.—He did not consider that the Bill's proposals would amount to the "direction" of doctors. All that would happen would be that when the Bill became law all the doctors in a particular area would be able to enter the public service in that area. An application by a new doctor wanting to enter a particular area would be referred to the Medical Practices Committee, a mainly professional body, which would have before it the question of whether there were sufficient medical practitioners in the area. If there were enough they would refuse the appointment. No one could argue that that amounted to direction. It would not affect the existing situation because doctors would be able to practise in the area to which they belonged, while a new doctor would have to find his practice in a place which was inadequately served.

With regard to remuneration, Mr Bevan said he was not in favour of a fully salaried service. He did not believe the medical profession was ripe for it. He believed that some kind of hedonism should prevail. There must be some degree of reward for zeal and some degree of punishment for lack of it.

It was therefore proposed that "capitation" should remain the main source from which the doctor would obtain his remuneration, but it was proposed that there should be a basic salary. One of the reasons for that was that a young doctor entering practice for the first time needed to be kept alive while building up his lists. The present system by which a young man got a load of debt around his neck in order to obtain a practice was an altogether evil one. The basic salary would take the place of that. The basic salary, however, must not be too large, otherwise it merely became "a disguised form of capitation."

He had made a further concession, continued Mr Bevan, and that was that the general practitioner—and the specialist—would still be able to obtain fees, although not from anyone on his own lists or panel or on the lists of those with whom he was working in "co-practice." He thought it would be impracticable to prevent a doctor from having any private patients at all because all they would succeed in doing would be to create a black market.

There ought to be no bar on anyone having advice from a doctor other than his own. Mr Bevan thought, however, that the amount of fee-paying on the part of the general population would be quite small. If the amount of fee-paying was great the system would have broken down. The whole purpose of the scheme was to provide free treatment. It was hoped that everybody would be on some doctor's panel when the scheme got working properly. "This is a field, however, in which idiosyncrasy is prevalent, and if a person wishes to consult another doctor there is no reason why he should be stopped. But the fact that a person can transfer from one doctor's list to another ought to keep fee-paying within reasonable proportions."

Specialists in hospitals would be allowed to have fee-paying patients. Unless some fee-paying patients were permitted there would be "a rash of nursing homes" all over the country. He believed that nursing homes ought to be discouraged. They could not provide the facilities of a general hospital. Specialists should be kept attached to the hospitals and not sent into nursing homes. Great importance was attached to the health service, which had been described in some places as an experimental idea. He wanted it to be more than an experimental idea.

Health Centres.—It was proposed to leave some personal services with the local authority and some with the health centre. Health centres would vary in size. There would be the larger ones with dental clinics, maternity and welfare services, and general practitioner consultative facilities, and the smaller ones where the practitioner could see his patients. Health centres were very valuable and would be encouraged.

in every way. Doctors would be encouraged to carry out their practice there. It would be some time before health centres could be established everywhere because of the absence of facilities.

Some thought the preventive services should be under the same authority. But a regional board of the sort needed would require the Albert Hall to meet in. There had to be a frontier at which the local authority joined the public health authority. There was no contradiction because some services were left to the local authority.

Consultations and Conferences.—There was an amendment on the Order Paper suggesting he had not sufficiently consulted the medical profession. He had met the medical and dental professions, pharmacists, nurses, midwives, local authorities, eye services, medical aid societies, and herbalists. He had had twenty conferences in all. Consultations had been very wide. His officials had had thirteen conferences in addition.

These consultations had produced a considerable amount of agreement. Opposition to the Bill was not as strong as it was thought it would be. On the contrary, there was considerable support for these measures among doctors themselves. As the proposals became known and the medical profession fully appreciated them nothing should please the doctor more than to realize that in future neither he nor his patient would have any financial anxiety arising out of illness.

There was an Opposition amendment about what was termed "interfering with charitable foundations." They were in fact not diverting endowments from hospital purposes. Teaching hospitals were going to be left with all their liquid endowments. Academic medical education would be far more free in the future than in the past. Furthermore, the £32,000,000 belonging to the hospitals would be used as a shock absorber between the Treasury, the central Government, and the hospital administration. It would be money which the hospitals could spend over and above funds provided by the State.

He was prepared when the Bill came to be examined in detail to consider whether any other relations were possible, but he thought that a Regional Board with an annual budget, with freedom to move inside that budget in disbursing that money to local management committees, would make hospitals responsive to local influence as well as to central direction.

The Minister concluded by saying: "I should have thought that all parties would be proud that Great Britain is about to embark upon an ambitious scheme of this kind. When it is carried out it will place this country in the forefront of all countries in the world in medical services. I myself take a very great pride and pleasure in being able to introduce this comprehensive and valuable measure. It will lift the shadow from millions of homes. It will keep many people alive who would otherwise have died. It will relieve suffering. It will produce a higher standard for the medical profession, and it will be a great contribution to the well-being of the common people of Great Britain."

The fifth annual report of the Birmingham Accident Hospital and Rehabilitation Centre shows a great increase in the number of admissions and attendances. The new patients numbered last year 24,686, almost double the figure for the first year of the hospital's existence, and the annual attendances in the rehabilitation department have multiplied four times in the same period. Nevertheless, the report complains that lack of medical staff has hindered progress. The hospital had no pre-war quota of medical man-power to determine its wartime strength, and the Central Medical War Committee allocated two surgeons, one assistant surgeon, one senior anaesthetist, and five junior medical officers to the hospital. "While this may have been considered reasonable in relation to the bed complement (210)," the report continues, "the fact remains that some 90% of the work of an accident hospital is out-patient work among ambulatory patients, whereas in some general hospitals the converse may well be the case." Moreover, an accident hospital must provide an active 24-hour-day 7-day-week service for the immediate treatment of new patients suffering from injuries. The junior medical officers had been recruited to the Forces, and at the time the report for 1945 was being compiled four of the senior members of the staff were to be called up. "So the closely integrated team, vitally necessary to deal with large numbers of patients, is to be broken up." Last year the Bernhard Baron Charities Fund presented £5,000 to the hospital for the development and maintenance of a burns unit.

SCOTTISH HOSPITALS AND POST-WAR DEVELOPMENT

SURVEYS OF THE FIVE SCOTTISH REGIONS

At the same time as the hospital surveys of England and Wales were proceeding, a survey of Scottish hospitals¹ was being undertaken on the initiative of the Department of Health. Scotland was divided for this purpose into five regions, based on Glasgow, Edinburgh, Dundee, Aberdeen, and Inverness, and the surveyors were appointed as follows: *Western*—Prof. J. M. Mackintosh, Prof. C. F. W. Illingworth, and Dr. R. J. Peters. *South-Eastern*—Mr. J. W. Struthers, F.R.C.S., and Dr. H. E. Seller. *Eastern, North-Eastern, and Northern*—Prof. R. S. Aitken and Dr. H. Hyslop Thomson.

Introduction

In a general introduction, subscribed to by all the surveyors, it is stated to be generally accepted that the organization of a progressive and co-ordinated hospital service for Scotland should be on a regional basis. The main voluntary and municipal general hospitals would form the keystone of the structure and be known as central hospitals; district general hospitals, mostly provincial voluntary hospitals of 100 to 200 beds, would act as hospitals of first reception for their own districts and undertake such medical and surgical work as did not require central facilities; country general hospitals, including E.M.S. hutted hospitals, would be available for the less urgent cases; and cottage hospitals would provide for cases falling within the competence of the general practitioner. "The most formidable problem of a hospital service is to provide accommodation for the chronic sick." The social urgency of these chronic cases cannot be ignored, and that is one reason for assessing general hospital requirements on a generous scale.

Grave shortage of general hospital beds is disclosed. The surveyors consider that in a closely knit industrial area the general hospital beds should number at least 8 per 1,000 of population; in the rural areas probably 4 to 5 beds would suffice. These figures do not include beds for the aged and infirm. Institutional provision should also be made for 75% of all confinements. The suggested hospital requirements, therefore, are:

General hospital beds 4-8 per 1,000 population.
Maternity hospital beds 4-5 per 100 births per annum.
Infectious diseases hospital beds 1.5 per 1,000 population.
Pulmonary tuberculosis hospital beds 2 per death per annum.

In general hospital wards the surveyors recommend wall-space of 8 ft. (2.4 m.) between patients. In maternity hospital nurseries 35 sq. ft. (3.2 sq. m.) per child is considered a reasonable standard.

Glasgow and the Western Region

The Glasgow Region has a total population of nearly 3,000,000. Eight sub-regions are suggested, the largest of which is centred on the city. One important step to be taken in the near future is considered to be the reinforcement of the staffs of the district hospitals outside Glasgow by part- or whole-time salaried appointments to be held by men of teaching hospital rank seconded from a Glasgow hospital.

"The extent to which such a service as this should be developed will depend to a large extent upon the character of the hospital service after the war, and we assume that the changes will be effected gradually as experience dictates. It appears to us that in the first place attention should be directed mainly to the appointment of general physicians and surgeons; but in the districts distant from Glasgow certain specialist appointments may also be needed."

Of Glasgow Royal Infirmary the surveyors say: "We have the feeling that at the time of our visit the staff of the hospital was over-pressed with work. With the evolution of a regional scheme it should be possible to relieve this pressure by having most of the ordinary hospital work of the county of Lanark carried out by the district hospital proposed for that county."

¹Scottish Hospitals Surveys. Edinburgh. H.M. Stationery Office. General Introduction, 6d.; Western Region, 2s.; South-Eastern, 1s. 6d.; Eastern, 1s.; North-Eastern, 1s.; Northern, 6d., in all cases net.

It is suggested that Victoria Infirmary, Glasgow, should be considered as a possible centre for postgraduate teaching, and that this hospital, with the Royal Infirmary, the Western Infirmary, and Stobhill and Southern General Hospitals should be the five central hospitals under the regional scheme. Certain suggestions are made for meeting a deficiency of 2,860 general beds in the Glasgow sub-region, principally by a new hospital of 1,500 beds at Newton Mearns. A high degree of priority should be accorded to the extensive additions required for maternity accommodation.

Proposals for other sub-regions are as follows:

Argyll—At perhaps half a dozen selected places, small combined units should be constructed, comprising a section to deal with general acute and chronic medical and surgical cases, a section for normal maternity cases, and an infectious diseases unit.

Bute—Similar proposals.

Ayrshire—A regional scheme would require for its full development greater use in common of specialist services by the appointment of specialists on a sub-regional basis to reside in the area and serve a group of hospitals.

Dumfries and Galloway—Seriously deficient in hospital accommodation of all types. A new combined district hospital should be built near Dumfries to deal with general cases, also to provide facilities for the treatment of acute diseases of the chest and as a clearing house for surgical tuberculosis and orthopaedic cases generally. As a long term programme the construction of a new maternity hospital near Dumfries is recommended.

Lararkshire—About 2,500 beds are required for general hospital accommodation. An interim plan is proposed which would utilize Motherwell County and Burgh Infectious Diseases Hospitals for general and maternity cases, and Stonehouse, Hairmyres, and Cleland as general hospitals, with Law Junction for infectious diseases only until a new hospital can be built.

Dunbartonshire—A district hospital should be built somewhere near Dunbarton, with a central infectious diseases hospital and a maternity hospital associated with it.

Renfrewshire—It is considered that the time has come when this county should be self sufficient in district services, while continuing to rely upon central Glasgow hospitals for medical treatment of a highly specialized kind. This makes necessary the appointment of a full time key surgical, medical, and specialist staff at the principal hospitals—a staff which should be resident in the areas served.

Stirlingshire and Clackmannan—This sub-region has a sufficiently compact population to warrant the development of a single fully co-ordinated hospital service, requiring the construction of a central hospital.

Edinburgh and the South-Eastern Region

The South-Eastern Region, with a population of just over 1,000,000, includes, in addition to Edinburgh, Dunfermline, and Kirkcaldy, 43 small burghs. Two hospitals, both at Edinburgh—the Royal Infirmary (1,161 beds) and the Western General (300 beds), may be classed as key or central; three others—Dunfermline and West Fife, Kirkcaldy, and Leith—may be included in the category of district hospitals and there are a number of other hospitals, general and special. The total bed accommodation in the South-Eastern Region is 8,671. The standard suggested for general hospital needs is 4 beds per 1,000 in rural districts and 8 in highly industrialized centres, giving an estimated total of 6,614, as compared with the present accommodation of 5,240 general beds. This additional 1,374 beds may seem high, but the surveyors justify it by citing waiting lists and the indications that many patients whose names are not on these lists would, if the accommodation were available, benefit from hospital treatment. It is also calculated that 880 maternity beds will be required to meet the needs of this area, the number of beds at present available, including even those in nursing homes, is only 529. The total accommodation for pulmonary tuberculosis in the region at present is 680 beds, and the estimate on the ratio of 2 beds for every death from this disease would give 912.

It is proposed to divide the area into four sub-regions—namely, the city of Edinburgh, the Border Counties, the County of Fife, and the Lothians. Patients from these four regions must depend on Edinburgh for those highly specialized services which can only effectively be provided in large central hospitals. Sub-region or district hospitals should be affiliated with the key hospitals in Edinburgh and share in the teaching of medical students. A serious effort should also be made to bring the chronic sick into the sphere of general medicine, and it is recommended that accommodation for these should be included in the general hospitals set up in the various

sub-regions. It is estimated that 3,326 general hospital beds will be needed in Edinburgh itself, 540 of them for patients outside the city, involving an addition to present accommodation (which is 3,295) of some 500 beds. Two central or key hospitals are proposed, one of them the Royal Infirmary and the other a new hospital to the south-west of the city.

For the Fife sub-region the long term aim should be to have two hospital centres, one to serve the western part and the other the eastern. The urgency of the need for adding to the hospital accommodation in this county is stressed. In the Lothians sub-region there should be eventually a complete hospital service, with two centres, for the western and eastern parts respectively. In the meantime the huddled annex of Bangour Hospital should be used as a centre to provide 600 beds for general purposes and obstetrics and 170 beds for infectious disease. In the Borders sub-region, on a long term policy, a hospital centre of some 600 beds should be erected; in the meantime the use of the E.M.S. hospital at Peebles would relieve the present shortage.

Dundee and the Eastern Region

In its general pattern the hospital service of this region must be based on the large hospitals in Dundee and a subsidiary centre in Perth, linked with the main centre for certain specialist and consultant services. Dundee Royal Infirmary and the local authority hospital at Maryfield should be replaced by a single new hospital on the outskirts of Dundee. This hospital would serve as the main teaching centre. The early establishment of an orthopaedic department and a department of psychological medicine in Dundee Royal Infirmary is recommended. The combined general hospital should include a children's block sufficiently large to undertake the work done at present at three institutions. A further recommendation is that King's Cross Hospital, Dundee, should become the central infectious diseases hospital for the region, and a new infectious diseases hospital should be built at Perth. For pulmonary tuberculosis a village settlement in association with Norenside Sanatorium is recommended.

This survey is different from most of the others in that it reports that accommodation for chronic sick is sufficient, or almost so, but half of it is in Poor Law institutions and does not approach hospital standards. Suggestions are made for the separation of chronic sick who are mentally normal from those who are mentally impaired. A short-term policy would secure over 800 extra beds for general and special hospital purposes by the inclusion of certain E.M.S. hospitals and annexes. New construction would be required for maternity accommodation at Arbroath, Crieff, Montrose, and Perth, with an adaptation at Maryfield Hospital, Dundee. Perth Royal Infirmary is declared to be a good and well equipped general hospital. Its urgent need is for a new maternity and a new out-patient department. With the strengthening of its specialist staff and an increase in size of the medical school at St Andrews it should be used increasingly as a teaching hospital.

Aberdeen and the North-Eastern Region

Most of the specialist members of the hospital staffs in this region are clinical teachers at the medical school at Aberdeen.

"The [Aberdeen] University is concerned to increase the number of clinical teachers in almost every department. It also wishes to undertake its share of the training of young specialists, for whom an increased provision of positions of the registrar kind is necessary. These developments must clearly be aligned with the development of the hospitals service of specialists, their numbers and their organization must be such as to provide for the adequate care of patients in all hospitals of the region and for the requirements of teaching, making a reasonable allowance of time for investigative work and for study leave. Throughout our recommendations we have borne these considerations in mind."

In pre-war conditions the medical staff at Aberdeen Royal Infirmary and at the Woodend (local authority) hospital was nearly adequate to meet the needs of the region, but the considerations just mentioned call for an increase. It is thought advisable to develop the principle of a joint staff shared between the two hospitals. The medical beds in the district and cottage hospitals will be adequate provided an increasing number of surgical patients is sent to the large hospitals in Aberdeen. The smaller hospitals could be used more than at present for the further treatment of patients who have already been examined and treated in the central hospitals. The surveyors hold that

general practitioners should not in future be encouraged to undertake major surgery. The majority of patients requiring major operations could be brought to the central hospitals in Aberdeen, though the Elgin district, 60 miles away, is judged to be too distant, and a surgical unit should be established in that town.

The extension of the Royal Aberdeen Hospital for Sick Children is regarded as so urgent that the surveyors recommend as part of their short-term policy the construction of a new block for premature babies, further provision for children suffering from infectious conditions, and extra accommodation for nursing staff. For the chronic sick they suggest an early start with new building on two sites in Aberdeen and a new hospital at Elgin.

An appendix to this part of the survey deals with the position in Orkney and Shetland, both of which should be linked up with the North-Eastern Region, though a link with the Northern Region in the case of Orkney would be a desirable alternative. A new cottage hospital at Lerwick, in Shetland, is recommended.

Inverness and the Northern Region

The Northern Region is the only one not based on a university town. It has, however, a long-standing association with Edinburgh, but the most marked local trend is from the Western Isles to the hospitals and specialists of Glasgow.

"The islands have long been served by ships from the Clyde, and their people have close personal and commercial ties with Glasgow. . . their medical practitioners are loud in the insistence that this association should be preserved in the medical service."

One of the principal recommendations of the surveyors is the establishment of a new maternity hospital in Inverness. The provision of maternity beds in the region is seriously short of the standard of 40 to 50 beds per 1,000 births recommended in the Report on Infant Mortality in Scotland, 1943. A maternity unit at Fort William, another to serve the Isle of Skye, and a cottage hospital to replace Belford, which is insufficient for the district and cannot be extended or adapted, is proposed.

With its dispersed population and widely separated centres this region presents a special hospital problem. In other ways, too, it has required special medical provision, as evidenced for the last thirty years in the Highlands and Islands Medical Service. In the view of the surveyors the region should in time look to Inverness as its main surgical centre, but there should be a link with Aberdeen also. To maintain contact with general practitioners it is suggested that specialists should visit the cottage hospitals if suitable accommodation can be provided for out-patient consultative clinics. The survey outlines a comprehensive provision for cases of pulmonary tuberculosis in which three of the existing hospitals would play a major part.

An air ambulance service has operated for some years between the Western Isles and the airport of Glasgow, and another between Stornoway and Inverness has been recently inaugurated. The surveyors urge the development of air ambulance facilities between outlying parts of the Highlands and Inverness as soon as air lines are extended.

IMPERIAL CANCER RESEARCH FUND

The annual general meeting of the governors of the Imperial Cancer Research Fund was held at the Royal College of Surgeons on April 17 under the chairmanship of Prof. H. R. Dean. The forty-third annual report stated that since the end of the war all but one of the scientific staff and all but five of the surviving members of the technical staff had been released from the Services and had returned to the laboratories. The treasurer, Sir Holburt Waring, reported that the total income for the year was close upon £25,000, and the sum received in legacies, amounting to over £57,000, was larger than in any previous year. At the same time a great increase of activity, involving new expenditure, was anticipated, and the council had appointed a committee to consider how the work of the Fund could best be intensified and expanded.

The director, Prof. W. E. Gye, in a statement on the work of the year, said that research had been continued in the same four fields—namely, in carcinogenesis, mammary cancer, hormones, and chemotherapy. One line of inquiry had been on the metabolism of sulphur in relation to the occurrence of cancer. Two general conclusions were to be drawn from the experimental data available. The first was that disturbance of sulphur metabolism impaired carcinogenic activity, the degree of inhibition of these two processes running parallel and the second, that sulphur played no part in the elimination of the carcinogens. Uncertainty as to this fact has hitherto proved a stumbling-block in the interpretation of the first phenomenon. The hypothesis that a primary action of carcinogens was their fixation to sulphydryl-containing constituents of an unknown nature in the cell was in harmony with all the findings so far accumulated.

Mammary Cancer

The experiments on mammary cancer are in their native slow and time-consuming. One piece of work to which Prof. Gye drew attention was directed to the elucidation of the intimate action of formulative stimuli on mouse mammary glands of high- and low-cancer strains. The attempt was being made, by careful experiment and detailed microscopical examination, to determine whether pathological changes in the breast must first occur or whether it was merely necessary for a certain stage of anatomical outgrowth or differentiation of normal cells to be reached before true cancers formed. Progress had been made in this difficult research, but results were not sufficiently complete to give definite answers to questions of vital importance to conceptions of the cancer process.

In the work on hormones one piece of investigation concerned the mechanism by which thiourea prevented the development of mammary cancer. Prof. Gye stated that the effect of the drug appeared to be more specific than that of simple under-feeding. Virgin mice receiving thiourea had long periods of dioestrus, and the mammary gland developed to a much lesser degree than in the control mice. In these ways mice receiving thiourea resembled the animals after ovariectomy. If, as has been suggested, thyroid secretion was necessary for the full activity of the pituitary-ovary hormone system, then the blocking of thyroxine synthesis by thiourea would be equivalent in some respects to functional ovariectomy, and its effect on the development of mammary cancer could be so explained. But there were conflicting phenomena which still needed explanation.

A large number of pure chemical substances have been tested for possible therapeutic effects in cancer, but so far none has been found to possess a special affinity for cancer cells. Partial regression of some human breast cancers after treatment with synthetic oestrogens having been reported, two members of the research staff investigated the action of stilboestrol on nine of the strains of transplantable tumours which had been found sensitive to treatment by colchicine, the alkaloid discovered in the National Cancer Institute of the U.S.A. to be a most potent mitotic poison, arresting cell division at metaphase in all kinds of cells. Pellets of stilboestrol introduced subcutaneously failed to influence the growth of the tumours unless the dosage was sufficient to induce toxic symptoms, including considerable loss of weight. It was therefore concluded that in this investigation stilboestrol had no specific action in inhibiting the mouse tumours employed, and that such inhibition of growth as occurred with relatively high dosages was the result of a non-specific action.

Some reference was made to the work done for the Government in the Fund's laboratories during the war. This included an investigation of the action of war gases on the eye, and especially the treatment of mustard gas burns. British anti-lewisite (BAL) was found to be a powerful antidote to all poisoning by trivalent arsenicals. "BAL produces an intracellular reversal of a pathological process of a new and striking character which has already been found to be applicable to such peacetime problems as the treatment of arsenical dermatitis and other forms of arsenical poisoning." It is hoped that a full publication on the whole subject of chemical injuries of the cornea may now be permitted, the eye presenting so good a field for experiment on the reactions of avascular tissues.

The Fund has now nine members of its scientific staff and three visiting research workers from abroad.

THE RETREAT, YORK, 1796-1946

In 1792 William Tuke, Lindley Murray, and other members of the Society of Friends proposed the establishment of a "retired habitation" near York for treatment of persons afflicted with mental illnesses. It was built through the donations of members of the Society, and was opened on May 11, 1796, when it received the name of "The Retreat." The original structure still remains as the central part of the buildings. The Retreat was the first institution in this country to initiate the humane treatment of the insane, and as a registered hospital for nervous and mental illnesses it continues its pioneer work. When first opened the patients and staff were known as "the family," and although great development and expansion have taken place since then, the family atmosphere has been jealously guarded throughout.

In celebration of the 150th anniversary there will be a gathering at the Retreat on the afternoon of Saturday, May 11; Mr. Arnold S. Rowntree will preside, Dr. Henry Yellowles will give an address entitled "Hitherto and Henceforth," and Mr. Anthony W. Tuke, a direct descendant of the founder, will plant a tree. On May 12 a service will be broadcast from the Friends Meeting House, Clifford Street, York, and on May 21 there will be a public meeting in London at Friends House, Euston Road, at 6.30 p.m., under the chairmanship of Dr. Cuthbert E. Dukes, the speakers being the Bishop of Coventry and Dr. Arthur Pool, medical superintendent of the hospital. The Friends Book Centre is publishing from that address a five-shilling booklet, *Light through the Cloud*, written by Mr. L. A. G. Strong after a visit to the Retreat. His purpose is to emphasize as a layman that methods in research and treatment are incomplete without an enlightened and friendly understanding of the stresses and strains to which human nature is subject.

EGHAM REHABILITATION CENTRE

The first residential industrial rehabilitation centre to be set up by the Ministry of Labour and National Service, at Egham in Surrey, is the subject of an excellently produced and illustrated pamphlet issued by the Ministry. The centre is on a hillside above the Thames, overlooking Windsor Castle and the playing fields of Eton, and consists of a country mansion on a 55-acre estate, with workrooms, class rooms, a medical block, and a gymnasium. Here are accommodated 230 men, either civilians or ex-Service men, between the ages of 16 and 50, for courses of from six to eight weeks. The aim of the centre is to help men who have completed hospital or convalescent treatment but are not yet fit for full-time employment nor even for full-time occupational training. Medical supervision is afforded by a resident doctor, the services of nurses and physiotherapists are available, and after a man has been put right in the physical sense, his preferences and aptitudes are studied with a view to his re-entrance into employment. "When a man leaves Egham, having completed his stay, he has already mapped out his future; he knows, with certainty and confidence, just what he is capable of, and just what he is going to do." It is stated that of 1,000 men who have passed through the centre during nearly two years, 500 have returned to their former jobs or to other suitable occupations, and most of the remainder to a Government or other establishment for further industrial training. Other such centres are contemplated.

Reports of Societies

SURGICAL TREATMENT OF DEAFNESS

At a meeting of the Liverpool Medical Institution on April 11, with the president, Dr. G. F. RAWDON SMITH, in the chair, Mr. A. TUMARKIN read a paper on "Recent Advances in the Surgical Treatment of Deafness."

Mr. Tumarkin dealt in some detail with the modern fenestration operation as perfected by Lempert. Though this operation was successful in a limited proportion of cases, and represented a real advance over all previous techniques, nevertheless, its value had been much overestimated by the popular press. In estimating the proportion of successful cases at about one in four, he made a plea for greater care in the presentation by surgeons of their results.

In the second part of his paper, on the surgery of chronic middle-ear suppuration, Mr. Tumarkin condemned radical mastoidectomy as a major and mutilating operation, which commonly failed to cure the suppuration and more often than not increased deafness. He described the operation of transmeatal atticotomy which he had designed nine years ago. This was an operation of precision performed with minute gouges

through an aural speculum. It utilized the external auditory canal as a natural shaft leading direct to the functioning structures of the middle ear. He claimed that the operation was superior to the radical mastoidectomy in many ways. It was a comparatively minor procedure and could be done in adults under local analgesia. The resulting operation cavity was minute and healed rapidly and permanently. After-care was reduced to a minimum and, above all, hearing was improved in a large proportion of cases. Mr. Tumarkin gave details of a group of 11 atticotomies recently performed on school-children. Otorrhoea had been present for from 2 to 12 years. In 9 cases a dry cavity was obtained in 2 to 6 weeks. In 5 cases the hearing improved. Pointing out that in nearly all cases the ossicular chain was destroyed by prolonged suppuration, he made a plea for early atticotomy as soon as it was clear that conservative measures could not succeed.

In the discussion which followed Mr. H. V. FORSTER said that he had not attempted the fenestration operation for otosclerosis. He had seen some good results follow Mr. Tumarkin's conservative transmeatal operation. Perhaps Mr. Tumarkin's comparison between this procedure and the radical mastoid operation done by the post-aural route had been a little severe. Though operating by the older method of approach behind the auricle, he preferred to be kind to the tympanic contents, especially in children. If necessary, one could work backwards from the attic instead of removing a wide area of the mastoid cortex. The war had revealed a large number of cases of chronic middle-ear suppuration in recruits called up for medical examination, though some of them heard remarkably well in spite of a chronic discharge.

RADIOGRAPHY OF PNEUMONIA

At a meeting of the Fever Hospital Medical Service Group of the Society of Medical Officers of Health on March 29, with the president, Dr. M. MITMAN, in the chair, Dr. THOMAS ANDERSON (Glasgow) illustrated the progress of consolidation in pneumococcus pneumonia by a series of radiographs.

Some of the patients showed a rapid clearing of the process so that a normal radiograph was obtained in two to three weeks. Other examples were shown, however, where even after the lapse of over five weeks marked evidence of consolidation was still present. In some of these the raising of the diaphragm and similar signs pointed to the possibility of collapse, but in the majority no such evidence could be found. The radiographic picture in these cases of delayed resolution was usually that of a feathery opacity with linear and circular markings. As a general rule the periphery cleared most slowly. The earlier figures of incidence which the speaker had recorded were supported by more recent statistics, which showed that the condition might occur in from 35 to 40% of patients over 35 years of age. Two points of importance were that eventually—sometimes after the passage of two to three months—a normal radiograph would be obtained, which suggested that the condition was not fibrotic; during this time many of the patients remained incapacitated. Secondly, patients whose initial consolidations showed the densest opacities in the radiograph took longest to clear.

Dr. Anderson then went on to deal with the radiographic appearances in cases of measles. In some patients the diagnosis of bronchopneumonia was not in doubt. But in a considerable number there were markings, particularly at the right inner base, which were in keeping with a diagnosis of partial collapse. The importance of the recognition of such cases was underlined by a series of radiographs from patients who were admitted with the diagnosis of pneumonia but who were found to have a collapse with bronchiectasis. In each case the starting point in the history was an attack of measles complicated by "pneumonia," after which the patient had had several pneumonic episodes. A plea was made for the more careful follow-up of suspicious cases.

A clinical meeting of the Medical Society of the L.C.C. Service was held at St. James' Hospital, Balham, on April 4, when the staff of the hospital demonstrated cases. There were 100 members present. The clinical demonstrations were followed by a discussion on some of the cases, which included a number in which oesophagectomy had been performed.

Correspondence

The Health Service Bill

SIR,—The initial difficulty most doctors experience in facing up to the National Health Service Bill is that all their training has been to fit them to fight for the lives and interests of others, and not themselves, so that they are rendered peculiarly vulnerable to this unwarranted attack upon their freedom and independence. "Unwarranted," I think, is the right word, because the "private enterprise," so despised of the Socialist doctrinaire, has played such an all-important part in making medicine the highly efficient profession that it is to-day.

If the Bill gave primary importance to the most pressing issue with which we are faced to-day—namely, lack of hospital beds, staff to run them, and better facilities for treatment—then we should feel more inclined to recognize that Mr. Aneurin Bevan knows what he is talking about. But no; this is relegated to comparative obscurity in comparison with the endeavour to make us swell the already indecently overcrowded ranks of the Civil Service. A possible failure in the health services makes the already gloomy list of Government failures in coal and housing pale into insignificance; nor will any promise as to the continuance of "private practice" reassure us, with the recent memory of the broken pledge to the approved societies.

Let us be quite clear: the seven Principles are vital; Mr. Aneurin Bevan refused to negotiate with us, let us refuse to co-operate with him unless he concedes these Principles.—I am etc.,

Crawley Down.

A. ORR-EWING.

SIR,—On the eve of what must surely be the most important Representative Meeting that has ever been held, and coinciding as it does with the second reading of the Health Service Bill in Parliament, may I plead with my fellow delegates, and with all the eloquence in my power, that they will now lift and separate from the main mass of arguable matter contained in the Bill those one or two points—there are no more and there may be fewer—upon which the profession may decide neither to argue nor to compromise, but at need to "stand and fight." It has been a weakness of past Representative Meetings, perhaps unavoidable in the absence of definite Government proposals, that there have been so many aspects of a scheme to revolutionize medical practice under discussion at the same time. In the mass of resolutions, at times overlapping or even conflicting, it has become difficult for the rank and file to see "the wood for the trees."

The confusional possibilities of what one of your correspondents calls a "cloud of words" are as endless as they are dangerous. An instance comes readily to mind. In the B.M.A. circular on the Bill under the heading "Family Practitioner Services," and repeated in the agenda for the Representative Meeting, the direction of doctors, the form of remuneration, and the disposal of practice goodwill are treated as three separate points. Surely on reflection it is apparent that they are corollaries of each other to the extent of being indivisible. The freedom of doctors to settle where they wish, payment by capitation fees, and the disposal by sale of practice goodwill taken together form a logical sequence, and a system that ensures the continued independence of the profession; taken separately they become meaningless symbols, of no practical value. In the same way their antitheses—direction, payment by salary, and abolition of practice sales—do not lead to a salaried service: they mean that it is here with us as an accomplished fact. I submit that here there are not three principles, but one, to be debated as one. Herein too, perhaps, is the outstanding principle of all. Indeed I am tempted to regard it as the only one which has emerged so far which justifies a fight. The B.M.A. is raising a defence fund; what for? Let us hear now, not in vague general principles, but in concrete terms, phrased in plain and simple language, and, if possible, without qualification.—I am, etc.,

Derby.

E. D. BROSTER.

SIR,—As a Socialist of sixty years' standing, a general medical practitioner in every class of practice, a supporter in the main of the present Government, an old friendly acquaintance of the Prime Minister, and a member of the B.M.A. for many decades, I should like to express my enthusiastic agreement with the arguments and with the proposals in Dr. W. M. Frazer's letter (April 20, p. 621).

A quarter of a century ago I wrote a book which was published under the title of *A National Health Policy*. Speaking of the panel system and free choice, I said:

"If a panel doctor feels that his patient needs visiting every day for six months, he is, at any rate, at liberty to do so without adding to the poverty of the home. If he does not rise to the opportunity then it is human nature that wants reforming. No system will tend to help much, least of all would a full-time salaried service, which would inevitably take away from the patient all initiative, control, and choice.

It is true that doctors who temperamentally take little pride in doing good work neglect it just as they used to do, but their neglect is not due to the panel system, and, fortunately, they form a very small minority. Moreover, the panel system has not only no responsibility for the creation of this neglect, but actually provides the only efficient remedies for it.

A remedy is rarely very effective in practice unless its application is in the hands of those who will gain by its success or suffer from that which it is devised to cure. If we had a system of salaried State doctors, it would still be the patient who would mainly suffer from the doctor's neglect, but it would have to be some public committee or State Department that would administer the criticism or inflict the penalty. The panel system has the great merit of placing the remedy largely in the hands of the patient. Flagrant cases are, in addition, treated by the public authorities with fine or expulsion, but the principal power lies with the panel patient himself. In the first place, he is free to choose whatever doctor in his district is of best repute, and if he is dissatisfied with his doctor and loses confidence in his skill or attentiveness he is free to leave him and choose another. There lies the true remedy for slackness and malpractice.

The doctor's income depends on the number of patients who select him and, having selected him, remain with him. Unfortunately, in the past the apathy of some of the doctors has been as nothing compared with the apathy of the great mass of panel patients. They have been apt to 'grouse' but not to act. They are at last beginning to realize their powers; and it is up to them, by a mere process of selection, to eliminate from the ranks of panel doctors the dwindling minority of slackers—the only ones who gain publicity.

Under the Insurance Act no provision has yet been made for specialist and hospital treatment, which nowadays forms so essential a part of a complete medical service. Until these additional services are included, and until the dependants of the employed population also come under the panel system, it cannot be regarded as complete even for its limited purposes. But so far as it goes it is, in my opinion, the best system yet devised, and I should much like to see it applied to other departments of practical economics.

It is not fair to debit the panel system with the fundamental defect of the National Insurance Act, which is that it is applicable to one class of the population only, affording a typical instance of class legislation. Nor is it a defect in the panel system itself that, even within that class, its potential benefits are available only to certain individuals in each family, or that, as stated above, it provides only an incomplete medical and surgical service, the more urgent and vitally important services being still entirely outside the insured person's reach.

Were the present panel service of general practitioners supplemented by an efficient and properly organized service of operating surgeons, and ophthalmic, gynaecological, and dental specialists, and adequate hospital accommodation, including all modern means of diagnosis; and were greater 'freedom of choice' given to the individual patient, the machinery simplified, and the connexion between the medical service and approved societies abolished, it is doubtful if a better system could at present be devised. The old-fashioned individual fee-hunting medical practice is condemned by experience as well as by the merest common sense. Under it, proper medical attention is barred for the majority of poor people. A salaried general practitioner service, on the lines of the Poor Law, would essentially reduce the position of the individual patient to a status difficult to describe other than as that of a pauper, for no comparison is possible between a 'family doctor' service and such services as the police or judicial. It would give increased power and security to the slackers in the medical profession, while discouraging hopelessly the more zealous. Keen men will do good work under any system, but the system is the best which places within the reach of the greatest number all the medical skill available, and gives the maximum encouragement to its exercise."

My views to-day are pretty much the same as they were then.—I am, etc.,

London, E.1.

HARRY ROBERTS.

SIR.—May I comment on a point in your leading article (April 20, p. 612) and on another issue that has been frequently raised in correspondence about the Bill. You suggest that the Minister should drop his salary proposal and see that doctors be remunerated on a capitation basis. If, however, the Minister did do this, would it be wholly fair to those doctors who, working single-handed before, have returned from the Forces to find their practices considerably diminished and their panel lists reduced by half or more? Thus one colleague, after some years away, sees his panel list reduced from 2,400 to 600; another from 1,700 to 700. If the Bill is passed all panel lists will presumably be dissolved and patients will be given afresh the duty of selecting a doctor. What real chance will the Service doctors have then of regaining their former practices? As we know, many people will, from inertia, tend to choose the doctor on whose list they were prior to the Act coming into force, with the result that those doctors who have been away will be at a considerable disadvantage. If this applies to once-established practitioners, how much more does it not apply to the young men and women about to start on their careers? The B.M.A. announces that it has them in mind and is making, or has made, arrangements to enable them to borrow money with which to buy a practice. This is very well, but if a man does not want to burden himself with a heavy debt—and one knows how heavy and harassing such a debt can be—then it's just too bad. He is, after all, free to struggle for a living as others have done before him. One cannot wonder that there are many who cordially welcome the proposal that a substantial part of our remuneration be by salary. It is idle to preach unity to a profession that is so divided by circumstance.

A different issue raised by many of your correspondents is this. They suggest that, when all may be treated "free," doctors will be swamped with the trivial complaints of patients who would not have attended had they been obliged to pay at each visit. Nothing, to my mind, is less likely. Many years of private and panel practice, and some recent experience as an Army medical officer, have but served to confirm what has repeatedly been proved before, and been conclusively demonstrated by the Peckham Health Centre, that, taking it by and large, sick people do not go to the doctor early enough. Not because they can't afford to—it is not only the poor who come to us with inoperable carcinoma or advanced disease—but because even when people know they are ill they are frightened of being told they are ill. We ought, then, to welcome the trivial complaint when we meet it, for we have seen too many patients die of what was first thought to be a trivial complaint or a neurotic symptom. And besides, if we pretend to be interested in our work we should be glad to study early symptoms and signs. For, as John Macmurray put it, "The man who goes to the doctor is a sick man."—I am, etc.,

London, E 1

M. MARCUS.

SIR.—Whatever one thinks of the new Health Service Bill there is one thing that stands out in startling relief—the fact that the Minister of Health has treated with contempt the members of the medical profession, in that he has declined any negotiation with its chosen Negotiating Committee. He has produced his Bill and has stated that its "framework" must stand. These are the actions of a dictator issuing an ultimatum.

When one studies this framework, "which must be accepted," one cannot but see clearly that it is not only a framework but is also a sepulchre designed carefully for the reception of the ashes of many things that have hitherto been held dear by the profession—individuality, initiative, independence, etc.—and it has also a special funeral urn for the ashes of the great and glorious traditions of our voluntary hospitals, dear to us also in a way that no other hospitals can be. It will be a very bad day for the moral and spiritual welfare of our country if its citizens are to be for ever deprived of the pleasure and uplift of contributing, to the succour of the sick and needy, gifts that are always twice blessed. How easily it could be avoided by the provision of grants in aid in order that our great voluntary hospitals should continue to lead, as they have always done, in the story of hospital progress.

Looking to the future under this Bill, what are likely to be the prospects of the profession with regard to the relationship of their various advisory committees to the Minister of Health? Is he compelled or is he likely to act on their advice? In view of his initial dictating the prospect is gloomy in the

extreme. I feel strongly that in resisting this Bill as it now stands the profession will be acting in the best interests of the people, and I am sure that the people generally wish us to remain, as heretofore, their own personal advisers, and not become mere civil servants whose first loyalty must be to the State. I cannot conceive that the profession will be so spineless as to accept tamely the Bill as it now stands, and I hope that all Branches will adopt the slogan: "No service under the Act until conditions of service acceptable to the profession have been reached as the result of negotiation freed from dictation."

—I am, etc.,

Egham, S E 9.

WILLIAM T. MILTON.

SIR.—Judging from the letters published in the *Journal* and from opinions expressed both in public meetings and in private, it appears that a considerable number of doctors object strongly on principle to certain proposals in the National Health Bill. Their objections are based on the belief that the proposals will tend neither to raise the standard of medical treatment nor to improve the health of the nation. The Bill sets us on the road leading to a full-time State salaried service, and the sacrifice of freedom and initiative thereby entailed should not be demanded by the Government until we are certain that a commensurate benefit will be derived from it by both doctor and patient.

Owing to the fact that the majority of general practitioners have commitments and dependants for whom they are responsible, they are not in a position to refuse service under the proposals of the Bill unless they know that a sufficient proportion of their colleagues are prepared to stand by them. If the B.M.A. should arrange a plebiscite in the form, "Are you prepared to work in the National Health Service as laid down in the Bill?" the majority will be obliged, however unwillingly, to answer "Yes." I venture to suggest that this difficulty might be overcome if questions were circulated in some such form as the following:

(a) Apart from economic reasons, are you in favour of accepting service under the National Health Service Bill as a matter of principle?

(b) If not, is your objection so strong that you would undertake to refuse such service provided that a sufficient number of your colleagues would unite with you in such a refusal?

Our leaders in the B.M.A., having studied the answer to these questions, would then be in a position to judge whether a sufficient proportion of general practitioners are prepared to stand together to make such action advisable, and could instruct members accordingly.—I am, etc.,

Stammore

H B WOODHOUSE.

SIR.—I do not dare say that I will not accept service under the Bill, but would willingly sign a statement that, providing 50% of doctors do likewise, I would refuse service. Many of us are afraid of being left "holding the baby," but such a document would probably be signed by 90% of the profession. The percentage agreeing would be the true percentage wishing to refuse service. Could not the B.M.A. try out such a document at once and see what happens.—I am, etc.,

Halesowen, Wores

H. W. BLAND.

SIR.—Recent correspondents have drawn attention to discrepancies in the Ministry of Health's Summary of the Proposed New Service as compared with the Bill itself. May I put forward a further point.

The Summary (para. 4) states that "all the service, or any part of it, is to be available to everyone" (*italics mine*). This appears to cover the right of a patient to consult a general practitioner outside the service, and not thereby deprive himself of hospital, consultant, and other benefits in the scheme. I can, however, find no reference to this privilege in the Bill itself.

Without suggesting that the treatment would be better, I believe there will be patients who, for personal and other reasons, prefer a private practitioner as their family doctor. It is of vital importance that such practitioners have access to the facilities of the service on behalf of their patients, and this right should be established, if possible, by a clause in the Bill. It may be suggested that the position could be secured by regulation, but regulations are too easily altered or cancelled by succeeding Ministers.—I am, etc.,

Sheffield, 10

HENRY BROWN.

Fallacy of the Health Service Bill

SIR,—May I be allowed to say that I believe the present attempt of the profession to resist regimentation is illogical. We are proposing to stop a symptom instead of the disease which produces it. The Government is committed to the task of gradually organizing the whole country for the purposes of mass production, and is therefore, from its own point of view, perfectly in order when it proceeds to the regimentation of the medical profession. Indeed, it is clear that, on the Government's own assumptions, the medical profession will form one of the most effective agencies in bringing about the desired organizing of the country's man-power. This the profession will do by virtue of its power of issuing or withholding certificates. If a cog stops arbitrarily in a machine the whole machine is thrown out of gear. Without a doctor's certificate no man in future will be allowed to leave his work. It being decreed that mass production through the agency of the State machine is henceforth to be Britain's aim in life, the organizing of medical certification will obviously have to be gradually tightened up until no one escapes the net. Hence the Health Service Bill is only a symptom. The disease is the drive towards the servile State. Therefore the doctors are surely the very people to point out the fallacy involved in merely "resisting the Bill."

Those of us who understand what freedom is and love it, and who are prepared to make some personal "sacrifice" in its cause, had better probably change our methods. Let us, I suggest, point out what is happening in the psychological sphere. That "feeling of frustration," to which many newspapers have lately been drawing public attention, would now seem to be deepening into an actual psychoneurosis, which is perhaps best described as *balked or thwarted personality*. And this again is apparently not only at the root of a major part of our growing insanity rate but also, via the "nervous system," producing many bodily ailments as well. If, therefore, we can demonstrate that the general advance of mechanization, standardization, and mass production by the State is bringing about more disease than it can ever possibly cure, the Government might conceivably be induced even now to drop its present Health Service Bill—nay, more, to reverse the general policy which is promoting so much disability in this country.—I am, etc.,

North Queensferry, Fife.

A. J. BROCK.

The G.P. and the Health Service Bill

SIR,—“Words,” said Voltaire, “were given to man in order that he might conceal his thoughts.” We have had a spate of words lately and are likely to have more. Even so, to ask an average doctor to put in a concrete form exactly what the N.H.S. Bill means to him is to ask an impossibility. He just doesn't know. Nevertheless, he is asked to be prepared to dive into his private treasury and be ready to part with anything from £25 to £100 to support some scheme, he doesn't quite know what. “Trust,” of course, is the essence of the contract. But some of us remember the slogan “Trust Baldwin,” and what a morass that led us into. Flocking to meetings is all very well, but does it prove anything except the existence of a gregarious instinct and a sheep-like tendency to be led by some dominating personality with a golden tongue? Let the orators beware when they think they are swaying those serried ranks of medical humanity in front of them. *Quot homines, tot sententiae*, and perhaps, as they file out, one hears an echo of old Omar, “but evermore Came out by the same door as in I went.”

I am no Socialist, and I have no love for Mr. Bevan or for any of his works, neither have I had any regard for any Minister of Health for the last 20 years, for they have scarcely troubled to disguise their own lack of interest in our profession. For that matter has the B.M.A. always been so perfervid about the interests of the G.P. as it appears to be to-day? The doctor-patient relationship is worked to death and savours slightly of cant. One feels sometimes that it is those doctors who wear themselves out in the interests of their patients who say least about it, and who would like to have a little of this burden taken off their backs. To pass some of our troublesome patients along occasionally to one of our colleagues would be as good as a holiday. Doctors are harassed by the ability of a certain section of the community to get medical treatment for next to nothing, and the result is that our waiting rooms are filled with

hypochondriacs and our nervous and physical energies dissipated listening to their doleful stories.

These troubles will inevitably get worse. But let us, for Heaven's sake, not always invoke the sacredness of the doctor-patient relationship. To the specialist who sees his patient once or twice this is all very touching, and so it would be to others did they not have to live for ever among them.—I am, etc.,

Hove.

G. L. DAVIES.

SIR,—A National Health Service Bill will inevitably be passed. There is a danger that we may lose precious time in debating Principles and freedoms when we should concentrate on briefing our medical Members and other M.P.s to advocate amendments.

Any scheme to lighten the financial burden of severe illness on the middle classes is welcome and overdue. Their health is primarily in the hands of the G.P., and my main criticism of the Bill is that it carries a few steps further the down-grading of the family doctor, a process that has been going on for twenty or more years.

I practised abroad for 14 years in places where necessarily a doctor had to rely on his own judgment, and I found on my return that, apart from the treatment of minor ailments, a general practice was mainly a distributing centre to direct patients to appropriate specialists and to hospitals and clinics. Success often appeared to be measured by the size of the panel and the speed with which patients could be supplied with a bottle or dispatched with the necessary specialist's letter. Hospitals, clinics, and specialists are all needed in abundance, and it is wonderful to think that they will be more easily available to the middle classes, but what interest does a G.P. get out of the service if he is to be converted into a medical clerk at a mass distributing centre or communal surgery, as the health centres will at first be?

Give us proper diagnostic clinics attached to the local hospital or sub-hospitals, with ancillary special departments and specialists in attendance and access to general-practitioner beds to work under the staff of the hospital. Give the family doctor a chance to keep alive his clinical acumen, and follow his patients as a friend and adviser through all stages of disease, encourage him to take his part in preventive medicine by employing him more in pre-natal clinics, child guidance clinics, rheumatism clinics, vocational psychiatric clinics, or whatever he may be most interested in or adapted for. Unless this is done no one will be interested in medicine as a career unless he can become a specialist, and you will have an ill-balanced service with many experts in restricted fields of therapeutics and an overworked rank and file of disgruntled disinterested medical clerks.

Demand for us more interest in our work and demand that we know definitely the conditions of service. Our salary and our compensation, and the method of assessing the latter, should be approved by Parliament and not left to be settled by regulations subsequently inserted by the Minister. If the compensation is adequate and fairly assessed, let us cease our opposition to the sale of goodwill. The old system of the sale of practices will never be an issue on which we can be united, as shown by the B.M.A. Questionnaire, in which 52% of all doctors who replied voted for its abolition. Whatever form the service may take the selling value of many practices will probably fall, and unless we are careful the Minister will be quite agreeable to let us miss the substance of £66,000,000 for the shadow of an unknown value later on.—I am, etc.,

Leigh-on-Sea, Essex.

H. W. TOMS.

Destruction of Freedom under the Bill

SIR,—As time passes it seems obvious that if the National Health Service Bill is passed into law it will completely destroy the freedom of the medical profession by any of four well-aimed blows.

The first and most fatal blow is that there has been no opportunity for the profession to save its liberty by negotiation before the Bill was presented. The second blow is that the Minister dictates the hospital, consultant, and general practitioner service, with the profession having no effective power to govern its own affairs above the level of local executive councils. These councils only have disciplinary and disbursement functions.

The third blow is the decision to prevent doctors owning the goodwill and freehold of their practices. Basic salary and

capitation fee, in whatever arranged proportion, are equivalent to salary and must lead to direction of practitioners and loss of independent medical attention. The public will suffer with their doctors by this outrageous proposal that doctors cannot own their goodwill as can other professions which are free, for the doctor will always have his eye on the State officials to be sure he is not being over generous to any of his patients. There could well be a general practitioner service of salaried type for those doctors who prefer this form of service and for those patients who do not object to communal surgery attendance, while leaving the majority of doctors the freehold of their practices. By this combination of salaried practice and freehold practice the public and the profession would safeguard their rights and avoid monopoly medicine.

The fourth blow is that the charitable bequests and endowments which have been bestowed on the voluntary and great teaching hospitals of the country are to be transferred to the ownership of regional and hospital governing boards under the control of the Minister, thereby striking a mortal blow at the independent consultant service in the hospitals, at their traditions, and at local pride, replacing private benevolence by official meidity. How much more practical it would be to give State subsidies in proportion to the needs of each voluntary hospital, in exchange for the acceptance by the hospitals of adequate central co-ordination of effort and perhaps of the purchase and supply of the numerous requisites for treatment and maintenance—I am, etc.

London W 1

GEORGE ROSSDALE.

Security

SIR,—It has been stated in some letters to the *Journal* that the doctors being released from the Services naturally want security. On this peg it is expected that demobilized medical officers will hang approval of the present proposals for a National Health Service. I submit that this conception of security, however fashionable and "progressive," is false.

In the last 15 years we as a nation have seen three forms of security attempted in the world. The first was that of acquiescence in evil, the so-called security of appeasement. This implied trusting that the good nature of our enemies would triumph if we did nothing to annoy them. In the meantime the money was coming in, and we were apparently economically more secure than we would be if we opposed the evil before us. Ultimately this system failed because it became clear that our principles would have to be sacrificed completely if we continued. The neutral countries did continue and ended in slavery. The French adopted the Maginot system of security, relying on complex static defences they forgot that security demands action, imagination, and inspiration by principles. Inertia is no guarantee of impregnability. They ended in slavery. Lastly we adopted the method of war, the method of insecurity and action. At a time when prudence demanded we keep our armour at home it was all sent to Egypt. Victory began soon after this rash act. Security, however uneasy, has temporarily been achieved by vigour and action, and I suggest that this must always be so. Security must be won, it cannot be dispensed except to slaves.

Even if it were true that a large majority of Service doctors desire security above everything—and it is doubtful—it does not follow even apart from the preceding argument that acceptance of the Bill will achieve it. Ministers of Health do not hold office for ever, and consistent progress is doubtful if they change frequently, nor is there any evidence that they will be very much concerned with our security. Those of us who are also looking for houses are not unaware that the source of the present Bill is the one which forgot that bricks are needed for houses. In fact this rather elementary architectural lapse makes us wonder if similar omissions in the much more complex and much more important task of building health are not perhaps concealed in the new Bill. It would be tedious to go into details but among the possibilities are that there may not be enough doctors, that housing and education are more important than health centres and certificates that our patients need servants and not masters that suffering humanity needs personal care not official patronage. Government action inspired by political motives as it usually is cannot be a substitute for personal action inspired by humane motives.

No, Sir, considerations like these do not create such confidence that we are eager to trust our security to any Minister, whatever his blandishments, financial or otherwise. It is not correct to assume that all we are waiting for is direction from on high, happy in the thought that we shall be well looked after and need never think for ourselves again. Some of us have had experience of this type of security. Are we to appease, thinking of our pockets, to be neutral and inert on grounds of security, or are we to act in accordance with fundamental principles—I am, etc.

P. A. GARDINER,
Sed. Ldr., R.A.F.V.R.

Selling Out the Profession

SIR,—An ancient profession such as ours is something which has come down to us through the centuries and is likely, so far as anyone can see to last for all time coming. It is something which one generation of doctors passes on to the next. It is far too big a thing for the doctors of this generation to hand over lock, stock, and barrel to the local authorities or the present Government. It is just conceivable, of course, though I doubt it, that at some dim and distant date when the world is a much better place than it is to-day the then generation of doctors might be justified in handing over our profession to some kind of international body as a gesture say, for international peace, but this would apply to the doctors not of one country only but of all.

Let us take long views in this matter. The local authorities have been concerned in the treatment of the sick in any great numbers only during the past 25 to 30 years. Now, it seems, most of this work is to be taken from them. Who would have dared to prophesy five years ago that this withdrawal of their powers would be contemplated to-day? Who knows but that in another 50 years the Government of this country will have nothing whatever to do with medical or surgical treatment?

Having given much thought, then, to the vital question exercising all our minds to-day I can come to no other conclusion than that it would be utterly wrong for us to give up our present right to buy and sell our practices, accepting in return for this sacrifice compensation at the hands of the Government. After all, a perfectly good medical service is quite possible without selling out our profession. I sincerely trust doctors will decide accordingly. I also hope they will reject the idea of a basic salary as payment on any other than a capitation basis would be almost as dangerous to our profession's welfare as a lost right to buy and sell its practices—I am, etc.

J. INGLIS CAMPBELL

Competition in a Whole-time Service

SIR,—In one of the explanatory paragraphs on the principles adopted by the Negotiating Committee appears the following statement: "It [a whole-time salaried medical service] might tend to replace competition for patients by competition to avoid them." The implication is that this would necessarily be bad. Is this really so? The panel doctor tends to take on many more patients than he can treat adequately. Is it not desirable to reduce somewhat the size of practices in the interest of the patient? These remarks apply with equal force to hospital out patients.

Secondly, in the past there has been a tendency (implicit if not explicit) to confine the number of entrants to the profession to those able to make an adequate living from the practice of medicine. The new Health Service Bill coupled with new educational provisions will make it possible to take in sufficient entrants to secure an adequate medical service for all. The abolition of competition for patients will result in professional welcome for, instead of opposition to, the flow of new entrants. Thirdly, if in the heat of the competition to avoid patients doctors are led to take a renewed interest in public health and hygiene will this be a bad thing for the patient?

Finally, those—and they are many—who experienced the doubtful bliss of long periods of enforced idleness as a result of the war will remember the enthusiasm with which patients when they finally did appear were greeted by whole-time salaried servants of the State,—I am, etc.

St. Mary Cray Kent.

BRIAN H. KIRMAN.

Naples Typhus Epidemic

SIR,—I was very glad to read Lieut.-Col. H. J. Crauford-Benson's notes (April 13, p. 579) on the Naples typhus epidemic. Many references have been made to the Naples typhus epidemic, in both the lay and medical press. In the majority of these the impression is given that the outbreak was terminated solely by the large-scale use of D.D.T. As Crauford-Benson points out, such statements require considerable qualification.

D.D.T. was brought into use at a relatively late stage of the epidemic. Large-scale dusting of the Neapolitans with this insecticide began at a time when it was evident that the initial methods employed had brought the epidemic under control. Its arrival in the field was nevertheless timely. This non-irritating, persistent insecticide is the ideal agent for dealing with an undisciplined populace, when regular bathing and laundry facilities are absent. The setting up of the mass delousing scheme, and the intensification of other control measures, so energetically pursued by the U.S. Typhus Commission, turned the defeat of the typhus enemy into a complete rout.

The Allied Armies and the civilians employed by them did not use D.D.T. They were protected by periodic dusting with insecticides containing pyrethrum or derris. This was done quickly and efficiently by hand-gun or power-gun apparatus. The number of civilians protected by inoculation was negligible, whilst when the epidemic was at its height the British Army inoculation rate was considerably less than 100%. The most important preventive measure employed was, therefore, the mechanical use of insecticide powders (for preventing lousiness as well as for treating infested individuals) using any efficient insecticide.

There was also a rigid military discipline, a highly organized scheme for case-searching, contact-dusting, and hospitalization, together with intensive military and civilian propaganda, and control of movement in and out of Naples. All these measures contributed to the cutting short of the outbreak and the prevention of spread to the Allied Forces. The control of civilian movement was, for various reasons, the least efficient part of the organization, and as a consequence many new foci of infection occurred in villages and towns outside Naples. Each of these had to be dealt with separately.

Many lessons were learned in Naples. First, the value of mechanical dusting methods was established beyond question. Secondly, the large-scale use of D.D.T. showed it to be a most remarkable insecticide, which, though somewhat slow in effect, possessed a residual action which prevented re-infestation. Finally, that this method of large-scale disinfection, invaluable though it is, must still be regarded as only one of the many measures to be put into operation to combat a typhus outbreak. It should also be mentioned that the whole-hearted co-operation of the British and American medical services, with the pooling of resources of personnel and equipment, contributed in no small measure to the success of the undertaking. An account of the epidemic, with particular reference to the preventive action taken by the British Army, is in course of publication, and in this emphasis is laid on the points mentioned above.—I am, etc.,

Late Senior Hygiene Officer, Allied Armies in Italy

Sjögren's Syndrome with Rheumatoid Arthritis

SIR.—In their article on iritis in the rheumatic affections (April 20, p. 597) Prof. A. Sorsby and Dr. A. Gormaz remark: "Moreover, rheumatoid arthritis seems to be part of the Sjögren syndrome." They refer to H. Sjögren himself (1940) in *Modern Trends in Ophthalmology* (ed. Ridley and Sorsby, p. 403). From the literature I also referred to the apparent association of rheumatoid arthritis with Sjögren's syndrome, in a paper regarding non-ocular features of Sjögren's syndrome (*Brit. J. Ophthalmol.*, 1945, 29, 299), but, though rheumatoid arthritis is fairly common in this country, I have never myself seen nor have I heard of an example (in this country) in which it has been accompanied by Sjögren's syndrome. It would be interesting to hear if Prof. Sorsby or Dr. Gormaz have.—I am, etc.,

F. PARKES WEBER.

Suprapubic Drainage of the Bladder

SIR,—Perhaps I have unintentionally diverted the important points raised by Mr. E. W. Sheaf (March 2, p. 331). It is well known that scarring from a suprapubic sinus, notably one of long duration, is troublesome in a subsequent prostatectomy. Being right-handed, the higher it is the greater my difficulty. Excision of the scar may involve opening the peritoneal cavity or wounding small intestine, which indeed seems to be attracted to it, together with the omentum, by the inflammation present. This attraction sometimes occurs when the sinus is situated low down.

It is generally recognized that sufficient space should be left for the lowest part of the Hamilton-Irwin apparatus to rest well above the bone, so that the fit of it is not interfered with and no excessive pressure has to be used. With this in mind the skin incision is planned accordingly. In my own apparatus this point did not arise, but that apparatus was troublesome to work, rather messy, and sometimes failed, especially on a phosphate-coated skin, so that its replacement by Irwin's apparatus was welcomed. The apparatus is now only of historical interest, as having been the first of such things, and its manufacture has been discontinued.

Puncture of the bladder can evidently be made either backwards and upwards or backwards and downwards according to an estimate of the size of the viscus after it has assumed its more permanent state. A small, thick-walled bladder, which requires rest to allay an intense and frequent desire to micturate, if punctured in a downward direction is apt to cause the trocar to skid. By stretching the lower end of the incision downwards such a bladder can be entered more easily in the upward direction. Whether the low position of the sinus causes more subsequent contracture of the bladder than a highly placed one is a difficult matter to decide in the presence of so many other factors.—I am, etc.,

London, W.1.

G. H. COLT.

Physical Therapy in Mental Disorder

SIR,—I appreciate Dr. Skottowe's criticism (April 6, p. 548) of the official recovery rate, but in my previous letter I also pointed out various factors which must be considered in assessing its value, and might have added others. For instance, in the Board of Control's annual report for 1928 the following passage occurs: "There was, as usual, a marked difference between the county and the borough mental hospitals with respect to recovery rates, the percentages being 29.7 and 37.1, respectively, a subject which, when opportunity presents, we propose to investigate." I do not know what the figures are now, but imagine the difference would be less, except perhaps in the more remote and sparsely populated areas. The fact that voluntary patients have been admitted to public hospitals for a number of years may cause a slightly increased recovery rate as compared with that of the past. While in a number of cases the term "voluntary" is hardly appropriate, yet it implies the admissions of some mild cases of a type which would be unlikely to be sent to mental hospitals in former years, and presumably usually favourable as regards prognosis.

Dr. Skottowe's "useful discharge rate" is of much interest. I have observed in recent articles on convulsive therapy a tendency to use the word "remission" rather than "recovery." The idea I had in mind when I wrote to you, Sir (March 23, p. 447), was that if convulsive therapy is of benefit, then there must be an increased recovery rate, and mistakes in diagnosis would not matter. If there is no increased rate that would imply that the patients who received shock treatment and recovered would have done so in any case. Owing to causes due to the war, I doubt if, at present, the Board of Control would be in a position to state, by the statistics they receive, whether this treatment has been of general benefit or not, but in the course of a year or two they should be in a position to do so. In an article in the *Journal of Mental Science* (January, 1944, p. 435) Dr. L. C. Cook summarizes by stating that the position of convulsive therapy in schizophrenia remains controversial, but that in affective states its value is not open to doubt. He does not, however, state whether in his opinion it has caused an increase in the general recovery rate. From Dr. Skottowe's high "useful discharge rate" in 1945, allowing for his comparatively small admission rate, it is evident that

very good results can be obtained by other means. While I have stated that it may be some time yet before the question can be settled, it would be of much interest if some medical officer, who has used the treatment extensively, would state whether he considers it has caused an increased general recovery rate in his hospital as compared with the rate for that hospital prior to the introduction of convulsive therapy, assuming that the types of the admissions were more or less constant.

In regard to Dr. Wright Lambert's letter (April 13, p. 589) my statement that Shaw Bolton found micrometric deficiency was made from memory of his work *Amnesia and Dementia*, which ran through the *Journal of Mental Science*, 1905-8. I note from an old medical directory that, in the same journal in 1901, he published "Histological Basis of Amnesia and Dementia," and that in the 1910 journal G. A. Watson published "Observations on Morbid Anatomy of Mental Disease." Knowing of the fine work done by the Lancashire asylum pathologists early in this century, and remembering especially that done by Drs. David Orr and R. G. Rows, I should be sorry not to have given due honour to Dr. Watson, but it would appear that Dr. Shaw Bolton was the first at all events to publish the matter. I am glad to know that Watson believed dementia praecox to be the result of an innate anatomical deficiency, and I certainly share his view. I would again urge that more pathological work be done, especially, if possible, to discover the early lesions in mental disease. The difficulties are many. There are few deaths, and it is not easy to get normal brains as controls. Post-mortem changes have to be allowed for, and artefact considered. Many people are now in favour of cremation, and if a person desires to be cremated, surely that person could not object to his brain being examined after death. It would certainly be of value to cerebral pathology if intelligent persons would allow this. It has occurred to me that the brains of war criminals who receive the death sentence could be removed very soon after death, and thus, after doing so much harm in life, they might do a little good after death! These latter remarks are a digression from the subject of convulsive therapy, but I am sure those who practise it would like to add to their knowledge of the histopathology of the brains they work upon.—I am, etc.,

Hastings.

HARVEY BAIRD.

Smallpox in the Vaccinated

SIR,—Dr. Killick Millard states (April 20, p. 625) that the child population is at present protected from smallpox by vaccination as the members of his staff on smallpox duty were. He suggests that the abolition of compulsory vaccination is not likely to be followed by an increase in the mortality from smallpox. It seems to me illogical to think that so large an increase in the unprotected population should not be followed by an increase both in the numbers and severity. At present our freedom from smallpox depends on the vigilance of our port sanitary officials. With the increase in air transport many infected people might arrive in this country apparently in perfect health.—I am, etc.,

Erdington

ROBERT ANDERSON.

Tropical Medicine

SIR,—In the *Journal* of Jan. 19 (p. 102) there are two letters under the caption "Tropical Medicine in the United Kingdom." Will you allow me to point out to your readers that probably the largest hospital in the Empire for tropical diseases is that situated in the 3,000,000 city of Calcutta. It is most efficiently staffed. It has many doctors taking the D.T.M. course who are also engaged upon research. The medical papers, records of treatment upon several million cases, the medical books published by the staff are a gold mine—vide Col. Napier's latest two-volume book.

My suggestion is that our future tropical disease specialists should have some training in that hospital, and that medical men at home should consult the papers and books mentioned before treating patients. If this suggestion be carried out some at any rate of the tragedies of the S.E.A.C. campaign might be avoided in future.—I am, etc.,

Bombay.

H. E. RAWLENCE,
Late Residency Surgeon in Kashmir.

"Congenital Malaria"

SIR,—With reference to Dr. I. G. Cameron's letter (April 6, p. 544), during the twenty years (Jan., 1922-Dec., 1941) that I spent in Singapore, in charge of the maternity hospital there, we had over 71,500 deliveries. Many cases of malaria were seen. In 1938 we had 241 cases of malaria in 5,551 deliveries. Yet in only one case—a European—can I say the malaria was transmitted before birth.

The patient, a primipara, was admitted with subtertian malaria, and on the sixth day after a normal delivery the child had fever and S.T. parasites were found in its blood. For some months after that blood was taken from the cord at delivery in all cases where the mother had, or had had, malaria, but in no further cases were the parasites seen. The marvel to me is that there are not more cases on record considering the intimacy of the two blood streams.—I am, etc.,

Lisburn, Ireland

J. S. ENGLISH.

"Cord Round the Neck"

SIR,—I am indebted to Dr. H. Tudor Edmunds for his observations (April 13, p. 588) on stillbirth in association with cord round the neck. I have noted the condition in two successive labours in a multipara. On the first occasion the woman was delivered of a female child, stillborn, attributable to the cord round the neck. In her next labour she was allowed to deliver herself naturally and gave birth to a male child, stillborn, attributable to the cord round the neck. I concluded that the cause of death in each case was asphyxia due to strangulation.—I am, etc.,

Harthill, Lanarkshire

S. H. P. McLAUCHLAN.

SIR,—I was much interested in reading the letter by Dr. H. Tudor Edmunds as I have had a similar case in which the cord was 5 ft. (1.5 m.) long and seven times round the neck; no interference with the circulation and the child was born alive. At the time I felt it was a record length of cord, but Dr. Edmunds's case beats it. I might mention that I once had a case where the cord was only 6 in. (15 cm.) long and yet round the child's neck once—in a primipara. The cord was stretched till it looked like a thick piece of string. It had to be cut before delivery could be obtained and the child naturally was dead. After the confinement was finished I measured the total length of the cord and found it exactly 6 in.

Another interesting record case I once had was where a woman in labour had a most abnormally large abdomen with such an enormous quantity of liquor amni—on emptying, it gushed on to the floor, ran out of the room, under the front door, down two steps, across the pavement, and just reached the gutter—I am, etc.,

Hove

E. MISTIN.

Spontaneous Hypoglycaemia

SIR,—With reference to the very interesting paper by Dr. N. G. Hulbert and Mr. R. J. McNeill Love on subtotal pancreatectomy in a case of spontaneous hypoglycaemia (April 20, p. 603) I would like to confirm that in such cases as described operation is fully justified. My own modest experience comprises only three similar cases, but I had the privilege to hear an unforgettable lecture by Prof. Evarts A. Graham of St. Louis, when he was a guest professor to this country in July, 1939, on what he called "The Applied Physiology and Surgery of Hypoglycaemia." May I quote the following points from the notes I made then, for what they are worth.

(1) The biggest tumours of the islets of the pancreas he (Graham) had seen at that time weighed 500 g. The smallest visible tumour to the naked eye had a diameter of only 5 mm. This is one of the reasons for the difficulty in finding the tumours in many cases.

(2) There are, incidentally, cases in which paroxysmal attacks of spontaneous hyperinsulinism exist without any apparent pathological change in the pancreas. In such cases it has to be assumed that there is a hyperfunction of normally shaped islet cells, and Prof. Graham removed up to 80% of the pancreas with good results in several cases. One patient, a small child, had been followed up for two years after the successful operation when he made his statement.

(3) Bigger tumours look, frequently, like a carcinoma macroscopically but turn out to be adenomas on microscopical examination.

(4) Post-mortem examination of the pancreas in cases of diabetes mellitus revealed tumours of the islets in a surprising number of cases.

(5) Two cases of Graves's disease of his own observation were mentioned. In one, paroxysmal attacks of hypoglycaemia began after thyroidectomy. On exploration an adenoma of the pancreas was found and removed. The hypoglycaemic attacks disappeared, but signs of myxoedema developed. In the second case of Graves's disease with low blood sugar and hypoglycaemic attacks the pancreas was explored. No tumour was found, but 80% of the pancreatic tissue was removed. After that not only did the hypoglycaemic attacks cease but the symptoms of the Graves's disease also disappeared.

I thought that these notes might be of interest as I have not seen them recorded at the time, and I hope that they reflect Prof. Graham's statement fairly correctly.—I am, etc.,

V. C. MEDVEI.

London, S.W.3.

Hospital Administration

SIR,—Your leading-article entitled "The Hospitals" (April 13, p. 575) contains a deliberate attack on medical superintendents and resident medical officers of municipal hospitals in general which does not appear called for on grounds of political expediency and is certainly quite contrary to the facts. We realize that in any considerable body of men there will usually be some isolated individuals who do not accept the standards of outlook and behaviour respected by the body as a whole, but we strongly repudiate and resent the suggestion that more than a few isolated examples occur. To appropriate words attributed to the Secretary of the British Medical Association five pages later in the same issue of your *Journal*: "Those who maintain that our profession is obstructive and stands in the way of a better health service either do not know the facts or are wilfully misrepresenting them for their own purpose." Or, Sir, are you advocating lay control of all hospitals, and thus opposing the fundamental B.M.A. maxim of "No lay control?"—On behalf of the Medical Superintendents' Society, we are, etc.,

J. J. O'REILLY, President,

R. KELSON FORD, Chairman of Council,

London, W.C.1.

JOHN M. MILLOY, Honorary Secretary.

The National Hospital, Queen Square: A Disclaimer

SIR,—During 1945 a group of private persons interested in ascertaining the cause of, and in finding a cure for, paralysis agitans, approached the National Hospital, Queen Square, and voluntarily forming themselves into a "Parkinson's Research Society," decided to raise funds to support research into diseases of the nervous system with special reference to paralysis agitans. At a meeting held at the hospital in July, 1945, the members elected a chairman and committee and, by donations and covenants, provided a sum of money which was handed to the hospital for the prosecution of the research in question. To this lay committee was added a member of the honorary medical staff of the hospital, while I became the honorary secretary of the society.

Steps had been taken to start this enterprise when, early in this year, it came to my knowledge, and to that of members of the honorary medical staff, that the chairman of the society, without previous consultation with the hospital authorities and upon his own initiative, was notifying members of the society and some sufferers from paralysis agitans, by letter, that in fact the cause of the disease had already been found to be bacterial and that a cure for it had been discovered. The name and address of a medical practitioner not connected with the National Hospital, in respect of whom these claims were made, was given in these letters, and patients were advised to put themselves under his treatment.

The board of management of the National Hospital is advised by its medical committee that these claims cannot be endorsed, and that it is not in the public interest that the hospital should collaborate with an organization that sponsors and gives publicity to them. I am therefore authorized to ask the courtesy of your columns for an announcement that the National Hospital dissociates itself wholly from the Parkinson's Research Society and from all claims made by it. The chairman of the society has been so informed and the two members of the society's committee who are connected with the hospital have resigned from it. The members of the society are being offered the return of their donations and subscriptions which were given to the hospital for the purposes of the proposed research.—I am, etc.,

H. EWART MITCHELL,
Secretary.

The National Hospital, Queen Square, W.C.1.

Obituary

SIR HAROLD STILES, K.B.E., LL.D., D.Sc.,
M.B., C.M., F.R.C.S.Ed.

Sir Harold Stiles, the greatly gifted Edinburgh surgeon, died on April 19 at his home at Gullane, East Lothian, aged 83. An Englishman, he went to Edinburgh as a student, and the whole of his professional life, apart from war service, was spent there. Twenty-one years ago, at the height of his fame, he retired from practice and teaching and, with a mind still keen and fresh, devoted himself to geology, and later, when physical activities had to be cut down, made botany his main interest. He joined the B.M.A. soon after qualifying and held office in Scientific and Clinical Sections at four Annual Meetings, including the presidency of the Section of Diseases of Children at Belfast in 1909.

Harold Jalland Stiles, son of Henry T. Stiles, M.D., was born in Lincolnshire, at Spalding, on March 21, 1863. His grandfather also had been a doctor, and from boyhood his heart was set on becoming a surgeon. After schooldays at Totteridge Park he entered Edinburgh University and graduated M.B., C.M. in 1885 with first place in the first-class honours list and the Ettles scholarship and Beaney prize. He spent some time as demonstrator of anatomy under Sir William Turner, took the F.R.C.S.Ed. in 1889, and was appointed assistant surgeon to the Edinburgh Sick Children's Hospital, to the Royal Infirmary, and to Chalmers Hospital. Before then he had paid a long visit to the Continent to gain first-hand knowledge of surgical practice in hospitals at Freiburg and in Berne, and his translation of Kocher's *Operative Surgery* became a standard textbook in this country. In 1919 Stiles, who had by then been for some time full surgeon to the Royal Infirmary, was appointed to the Regius Chair of Clinical Surgery at Edinburgh in succession to Prof. Francis Caird, and when he retired from the chair in 1924 he became Emeritus Professor and many high tributes were paid to him. Not only did he win early distinctions at Edinburgh, but in 1895 the Royal College of Surgeons of England awarded him the first Walker prize as having done the best work during the previous five years in advancing knowledge of the pathology and therapeutics of cancer. In the 1914-18 war he served in the R.A.M.C. with the brevet rank of colonel, and was appointed a member of the commission which investigated the administration of military hospitals in France and Britain; he also did fine work for wounded soldiers at Bangour Hospital, especially in the realm of orthopaedics.

Sir Harold Stiles was a past-president of the Royal College of Surgeons of Edinburgh and of the Association of Surgeons of Great Britain and Ireland; an honorary graduate of the Universities of St. Andrews, Edinburgh, and Leeds; an honorary Fellow of the American Surgical Association and the American College of Surgeons; and an honorary member of the American Medical Association, the British Orthopaedic Association, and the Royal Academy of Medicine, Rome. He was created a knight in 1918 and a K.B.E. in 1919; he was also Extra Surgeon to King George V in Scotland. These and other honours reflected the fame he had won in the eyes of colleagues at home and abroad. Harold Stiles's power of intense concentration, his self-reliance in judgment and action, and his technical brilliance as an operator won him a unique place in the Edinburgh Medical School. Few surgeons of his time can have equalled him in sheer craftsmanship or in mastery of the foundations of good surgery. He gave up practice in 1925 in a manner characteristic of the man, making

[Press Portrait Bureau]

a clean cut from professional and public ties, except those of friendship. In a personal letter written nine years ago he described himself as "not idle though one of the unemployed," and of his geological pursuits he wrote: "Living in the past is a privilege of old age, and my hobby carries one back for about 2,000 million years and gives me more scope for reflection and imagination than surgery did!"

S. P. JAMES, C.M.G., M.D., F.R.S.

Lieut.-Col. I.M.S.(ret.)

Lieut.-Col. Sydney Price James died at the age of 74 on April 17 at Chichester after a short illness. He was a distinguished officer of the Indian Medical Service, who engaged in research work throughout the greater part of his service in India and after his retirement in 1918; especially on malaria, on which he became one of the leading experts.

He was educated at the St. Mary's Hospital Medical School and took the M.B. degree of London University in 1895, the M.D. in tropical medicine in 1906, and the D.P.H. in 1907 while on leave from India. He entered the Madras Medical Service in 1896 and saw active service on the North-West Frontier of India in 1897-8 and in the Boxer Campaign in China in 1900-1. He then joined the recently instituted bacteriological department of research workers, and was nominated by the Government of India as a member of the Royal Society's Malaria Commission in India during 1902-3, an appointment which influenced his whole subsequent career. During this period he was the first to describe a non-malaria three-day (pappataci) fever in the Punjab and to differentiate it from malaria. While working in Madras he had independently discovered that the infection of filariasis is due to inoculation of the young worms through the bites of mosquitoes, and not through water as Manson had suggested. In 1904 James received the coveted Simla post of Statistical Officer with the Government of India; this he held for many years, during which he made short inquiries on kala-azar and on the danger of yellow fever being carried to India. He also wrote a valuable book in 1909 on *Smallpox and Vaccination in India*. Previously he had published in 1902 a report on the causation and prevention of malarial fevers, in which he recorded his work with the Royal Society Commissioners, and in 1904 he wrote with W. G. Liston a monograph on anophelid mosquitoes in India; both of these appeared in further editions. He also edited *Paludism* in 1910-14. During the 1914-18 war he served in an administrative post in Mesopotamia. He retired in 1918 from the I.M.S., but was soon appointed adviser on tropical diseases to the Local Government Board (now the Ministry of Health) and he served on the League of Nations Commissions on malaria in Eastern European countries and on Colonial Office inquiries in East Africa. For his many public services he was awarded the C.M.G. in 1935.

Col. James was a quiet little man, who was more interested in preventive than in curative medicine. During his long service in Simla he was responsible for compiling the annual sanitary reports of the Government of India and wrote valuable summaries of recent advances in medicine for those reports, but he took every opportunity of engaging in research. After he came to work in England he was in charge of the Horton laboratory for making use of malaria therapy for mental diseases, which gave him more time for research. He made such good use of these opportunities that he was elected a Fellow of the Royal Society in 1931. After retiring from his appointment with the Ministry of Health he transferred his energies to the Moltano Research Institute at Cambridge, and latterly lived at Chichester. He thus led a full and useful life with a great variety of interests. He held office as vice-president of the Section of Tropical Medicine at the Annual Meeting of the B.M.A. at Cambridge in 1920 and as president of the Royal Society of Tropical Medicine and Hygiene in 1937-9. He married early in his service and his wife survives to mourn his loss.

SIR RICHARD CHRISTOPHERS, F.R.S., writes:

The announcement of the death of Lieut.-Col. Sydney Price James will be received with feelings of deep regret by malariologists all over the world. His contributions to knowledge of malaria were very great, and especially in the field of the scientific study of drug treatment and prophylaxis he was undoubtedly the first authority. It was not, however, only in the recording of facts about malaria

that James's influence made itself widely felt but in the fresh approach and the spirit of interest and enthusiasm which he infused. Looking back one realizes how wide a field in the course of years his activities covered. In his early days we find James almost the first to bring mosquitoes, so to speak, on to the screen as living, interesting creatures—delightful simple descriptions, almost the first ever made—the tiger mosquito and its larva—all very elementary now but quite new then. In 1904 he wrote, with Liston, that early mosquito classic the *Monograph of the Anopheline Mosquitoes of India*, with its plates by Turkud giving accurate pictures of every then known species of Indian anophelids. In that year he was appointed Statistical Officer with the Government of India. But he still continued his interest in mosquitoes, adding much that was new to the second edition of the monograph and later being editor of *Paludism* and active in bringing about that golden period of research which followed on the Imperial Malaria Conference at Simla in 1910 when the Provincial Malaria Organizations were formed and for the first time the broad facts about malaria in India were ascertained. Later he is on deputation from the Indian Government to visit Panama and seaports between that country and India and to report upon the serious question of how far there was danger from opening of the Panama Canal of the introduction of yellow fever into India—an investigation which led to his being later one of the foremost authorities on this disease and president of the Yellow Fever Commission of the Office International d'Hygiène Publique, Paris. In 1916 sickness contracted in Mesopotamia was followed by his retirement from the Indian Medical Service and his appointment as adviser on tropical diseases to the Local Government Board (now the Ministry of Health). The malaria therapy centre at Horton, constituted towards the end of the 1914-18 war, owed its origin and later development to him. It might so easily have become a centre for routine treatment of general paralysis by blood inoculation. Instead it has been the chief centre in this country undertaking systematic malaria research, investigating clinical aspects of the disease, studying relapses, dealing scientifically with the principles of treatment, testing out new antimalarial drugs, and much else. At Horton was finally established the validity of *P. ovale*. From Horton came the first indications of the existence of strains in malaria—a fact now fully accepted. It was James who brought forward the idea of "causal" prophylaxis, not a very good name in some respects, but embodying an idea that has grown in importance and may eventually be the final answer to prophylaxis of malaria. Then how much should we know of the indigenous malaria of this country were it not for the interest infused by James?

When the League of Nations was formed James threw himself with all his active mind and energy into the wide investigations then made by the Malaria Commission of the League. So also in the war just over, though then retired from his post in the Ministry, he nevertheless again threw himself into the arena, ever intensely concerned in everything to do with what he regarded as the most urgent of all problems connected with malaria—viz., effective prophylaxis and ability to cure the disease. Certainly few can show such a record of work and results as James.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

G. W. Harris, M.D., has been reappointed university demonstrator in anatomy with tenure to Sept. 30, 1948, and M. M. Bull, M.B., B.Chir., with tenure to Sept. 30, 1947. J. Davies, M.B., Ch.B. Leeds, D. A. W. Edwards, M.B., B.Chir., and J. D. Green, B.M., B.Ch. Oxf. have been appointed university demonstrators in anatomy for three years from Jan. 1, 1946.

The Professor of Anatomy gives notice that applications for the Marmaduke Sheild Scholarship in Human Anatomy are to be sent to the Registry before May 20 in the present term.

In March the titles of the degrees of M.B., B.Chir. were conferred by diploma on M. A. Brown, of Girton College.

UNIVERSITY OF LONDON

The following candidates have been approved at the examination indicated:

ACADEMIC POSTGRADUATE DIPLOMA IN MEDICAL RADIOLOGY.—*PART I*: P. H. Beamish, M. C. Connell, S. Curwen, M. A. Egan, E. E. Faerber, E. H. Hanson, H. S. Hogg, Ethel P. Johnson, Mary J. C. McIntosh, L. L. McKelvie, M. Mandelstam, J. J. Nally, B. Naved, P. E. S. Palmer, G. W. Pimblett, Ella Preiske, E. J. Richardson, M. P. Shapiro, W. V. Taylor, B. C. H. Ward.

UNIVERSITY OF GLASGOW

The Senatus Academicus proposes to confer the honorary degree of Doctor of Laws on Archibald Wilson Harrington, M.D., formerly Muirhead Professor of Medicine in Glasgow University; on Sir Edward Mellanby, K.C.B., M.D., F.R.S., Secretary of the Medical

Research Council; and on Ronald Aylmer Fisher, F.R.S., Professor of Genetics in the University of Cambridge. The graduation ceremony, at which these and other honorary degrees are to be conferred, will be held on June 19.

At a graduation ceremony on April 13 the degree of M.D. was conferred, with high commendation, on J. B. Morrison.

UNIVERSITY OF DUBLIN

Adams Andrew McConnell, M.B., B.Ch., F.R.C.S.I., has been appointed Regius Professor of Surgery in the University in the room of the late Sir Arthur Ball.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

Election of Fellows

At a quarterly comitia of the College held on April 25, with the President, Lord Moran, in the chair, the following were elected Fellows:

T. F. Fox, M.D. (London); Perrin H. Long, M.D. (Baltimore, U.S.A.); R. E. Roberts, M.D. (Liverpool); Andrew Topping, M.D. (London); G. C. Linder, M.D. (Rondebosch, S. Africa); K. S. Hetzel, M.D., F.R.A.C.P. (Adelaide, S. Australia); H. S. Le Marquand, M.D. (Reading); Gladys M. Wauchope, M.D. (Hove); Lord Amulree, M.D. (London); L. C. Hill, M.D. (Bath); Wilfred Evans, M.B., F.R.A.C.P. (Sydney, N.S.W.); F. B. Parsons, M.D. (Cambridge); E. W. Anderson, M.D. (Exeter); E. G. Robertson, M.D., F.R.A.C.P. (Melbourne, Victoria); G. G. E. Smyth, M.D. (Blackburn); R. Freeland Barbour, M.B. (Bristol); Arthur Willcox, M.D. (Sidecup); A. Morton Gill, M.D. (London); F. Avery Jones, M.D. (London); Alice M. Stewart, M.D. (Cardiff); C. G. Parsons, M.D. (Birmingham); W. T. Cooke, M.D. (Birmingham); Ian Gordon, M.B. (Aberdeen); G. W. Hayward, M.D. (London); E. E. Pochin, M.B. (London); J. W. Aldren Turner, D.M. (London); K. O. Black, M.D. (Poona, India Command); Alan Kekwick, M.B. (London); E. R. A. Merewether, M.D. (London); A. J. Orenstein, M.D. (Johannesburg); J. Douglas Robertson, M.D. (London); Emanuel Miller, M.R.C.P. (London); Robert Cruickshank, M.D. (London); F. R. G. Heaf, M.D. (London); John McMichael, M.D. (London).

Prof. James Mackintosh was appointed to represent the College at the Health Congress of the Royal Sanitary Institute and Prof. Alan Moncrieff on the Medical Advisory Committee of the Colonial Office. Lord Moran was elected a representative of the College on the governing body of the British Postgraduate Medical School and Dr. W. S. C. Copeman on the committee of management of the Chelsea Physic Garden in succession to the late Dr. J. D. Rolleston. Dr. G. E. S. Ward was appointed an external examiner in medicine for the Fellowship Examination of the Faculty of Radiologists.

On the nomination of the Council the following were elected representatives of the College: Dr. F. S. Langmead on the Central Midwives Board; Prof. James Mackintosh and Dr. I. E. McCracken as examiners for Part I of the D.P.H., and Dr. J. Bishop Harman on the Committee of Reference and the Central Medical War Committee.

The President reported that he had nominated a committee to consider the prevention and management of rheumatic heart diseases.

Membership

The following candidates, having satisfied the Censors' Board, were elected Members:

M. Abdel-Malik, M.B., M. Z. Ahmad-Soudan, M.B., F. P. Antia, M.D., A. Batty Shaw, B.M., W. D. Brinton, B.M., J. B. Cavanagh, M.B., J. Colover, M.B., G. M. Colson, B.M., E. Cronin, M.D., J. H. Dadds, M.B., A. J. Daly, M.D., P. R. C. Evans, M.B., F. J. Flint, B.M., P. B. S. Fowler, B.M., J. P. Gemmell, M.D., P. W. Hardie, M.D., H. F. Harwood, M.D., M. A. Jallil, M.B., W. E. J. Jones, M.D., J. W. Landells, M.B., E. H. Larkin, M.B., S. H. Llewellyn Smith, B.M., M. J. G. Lynch, M.B., M. B. Matthews, M.B., B. E. Miles, M.B., R. I. Milne, M.B., J. D. N. Nabarro, M.B., Lucy M. B. Nelson, M.B., D. P. Nicholson, M.B., S. Olecky, M.B., W. S. Peart, M.B., L. G. Picciotto, M.B., T. R. E. Pilkington, M.B., R. J. Pugh, M.B., Elizabeth V. Rohr, M.B., D. W. Smathers, M.D., P. N. Taneja, M.D., D. Taverner, M.D., D. J. Thomas, M.B., C. H. Warren, L.R.C.P., Marcia I. P. Wilkinson, B.M., K. A. A. Wray, M.B., C. H. Wyndham, M.B., R. K. W. Yang, M.B., J. Yudkin, M.D., J. V. Zammit-Maempel, M.D.

Licences

Licences to practise were conferred upon the following 125 candidates (including 32 women) who had passed the Final Examination in Medicine, Surgery, and Midwifery of the Conjoint Board, and who have complied with the necessary by-laws:

Queenie M. F. Adams, J. Aminoff, R. Armatage, J. N. Badham, J. K. Baird, Roberta S. J. Baker, D. V. T. Baldwin, D. H. Barnbrook, M. S. Bentley, A. J. Berman, P. Blackledge, A. G. Brown, J. Butler, A. R. C. Butson, Margaret J. S. Caten, Monica L. Chalmers, J. Chalom, G. B. Chamberlain, A. O. Chase, I. C. Church, J. F. Cleobury, Betty L. Coles, A. P. Cornwall, L. T. Cotton, J. Cox, M. I. Cox, J. L. Crammer, D. T. Crook, R. R. Davis, Nina Dawson-Reid, J. F. Delafresnay, D. J. Dennison, W. R. Denny, R. de A. Denton-Cardew, Margaret M. Dickinson, J. H. O. Earle, Hilda A. Elman, J. B. D. Evans, H. S. Eyre, A. J. Fournier, Joan E. Garside, J. Z. Garson, Dorothea E. Garwood, Marjorie Golomb, F. R. Goodwin, R. V. H. Goulder, Joyce F. Grant, I. R. Gray, E. P. Hall, Joyce Hanscomb, Dorothy A. Harvey, J. R. Hawkins, T. D. Hawkins, L. M. Henry, C. W. J. Hington, K. J. Hoffmann, Philippa A. Howard, D. H. Isaac, J. P. Jackson, Gillian F. Jacob, Maureen B. Jeffrey, P. Jordan, Ellen M. Knight, Barbara M. Leach, G. L. Leathart, R. E. Leighton, T. R. Littler, Joan N. Mackover, H. R. Macleod, B. MacMahon, Anne Maguire, I. W. H. Mansfield, Joan C. Mason, J. W. B. Matthews, J. G. Millichap, M. L. Montagnon, J. D.

Montagu, R. A. Morris, A. H. G. Murley, D. P. North, H. Nussbaum, D. W. J. O'Neill, O. Pacovsky, Hilary C. Parton, F. Patuck, Phyllis H. Phipps, Margaret H. Pond, M. J. Raymond, J. A. Reynolds, E. F. W. Richards, Stella M. Ring, K. D. Roberts, G. Robins, M. Roper, J. D. S. Rowntree, F. C. W. Royle, J. N. Sampson, P. R. B. Sankey, R. O. K. Schade, O. C. A. Scott, R. F. M. Seaton, F. W. R. Seward, V. E. Sherburn, Alice M. Sibby, D. R. Smith, Pamela M. Smith, J. Sutcliffe, Bernice A. Tanner, J. J. Teeuwen, R. G. Thomas, L. F. Tinkler, J. K. Trotter, J. Walsh, J. I. Wand-Tetley, E. H. P. Warburton, Sylvia D. M. Waters, W. R. Wardill, A. P. H. Wilkison, R. H. L. Wolfsohn, F. J. Woodley, Ann Wyatt, H. W. Wyile, P. M. Yap, Stella Yeomans, S. C. B. Yorke.

Diplomas

Diplomas in Ophthalmic Medicine and Surgery (22) and in Physical Medicine (3) were granted, jointly with the Royal College of Surgeons of England, to the successful candidates whose names were published in the report of the meeting of the Royal College of Surgeons of England in the *Journal* of March 30 (p. 509).

Diplomas in Medical Radio-Diagnosis, in Medical Radio-Therapy, in Tropical Medicine and Hygiene, and in Child Health were granted, jointly with the Royal College of Surgeons of England, to the following successful candidates:

DIPLOMA IN MEDICAL RADIO-DIAGNOSIS: J. C. Bishop, J. D. Dow, N. E. Dunn, E. E. Faerber, M. H. Fainsinger, K. H. Gaskell, H. B. Howell, G. B. Locke, V. G. Peckar, G. W. Pimblett, G. L. Rolleston, O. E. Smith.

DIPLOMA IN MEDICAL RADIO-THERAPY: W. G. Evans.

DIPLOMA IN TROPICAL MEDICINE AND HYGIENE: J. G. Makari, G. J. Murray.

DIPLOMA IN CHILD HEALTH: Enid I. M. Addenbrooke, Sheila W. Anderson, Muriel C. Andrews, Margaret M. Ballantine, Laura M. Bates, D. W. Burnford, Ethel F. Caplan, S. Chaudhuri, J. D. Cruickshank, Barbara S. Davies, A. N. D'Cotta, Elizabeth S. A. de Wit, Constance M. Duddle, S. P. Dundon, H. L. LeV. D. Durell, Frances M. Earle, B. E. Finch, J. E. Francis, Margaret Garnett, Elinor Ginsbury, P. R. Headley, G. Hildick-Smith, Dorothy D. Jones, H. M. Khan, S. Kowaty, Winifred M. Markham, Nancy S. Marshall, B. McNicholl, Margaret Middleton, Joyce B. Mole, D. Naidoo, Catherine A. Neill, C. O'Donovan, C. Ounsted, Eileen E. Perry, Mildred I. Pott, T. H. Powell, Maïre M. Pugh, J. Revans, A. P. Roberts, Doreen C. B. Stevenson, G. L. Stumbles, Janet Sutherland, P. N. Taneja, Megan J. Tanner, Mary Townsend, Morwenna M. Tunstall-Behrens, Patricia B. Vicary, J. R. D. Webb, Mary E. Wehner.

Medical Notes in Parliament

Budget Concessions

In the Budget statement for 1946-7, made on April 9, Mr. DALTON proposed that the earned income relief from income tax should be increased to one-eighth, subject to a maximum allowance of tax of £150. The increase would operate for the whole year, but effect would not be given to it until the second half of the year. The allowance in respect of a wife's earned income would be increased from a maximum of £80 to a maximum of £110. It was proposed to free from duty certain cocoa materials used for the production in this country of theobromine. Exemption from purchase tax was proposed for epidiascopes. The duty would be reduced to 33½% of the wholesale value on bags, pouches, and similar receptacles, of leather, hide, or skin, designed for use solely for the purposes of any trade, profession, employment, or vocation, and unsuitable for use for other purposes. A similar reduction was made in photographic cameras, enlargers, projectors, lenses, and unexposed sensitized photographic paper, plates or film.

Infantile Paralysis in Singapore

Mr. BELLENGER reported on April 9 that he was aware of an outbreak of infantile paralysis in Singapore. Up to March 26 17 Army cases with 6 deaths had been notified. Thirty-three cases with 6 deaths occurred in the other Services. The outbreak was first reported in a signal dated Feb. 20. A research epidemiologist nominated by the Medical Research Council left by air on March 2 to investigate the outbreak, and, in preliminary reports dated March 13 and 19, gave his opinion that the outbreak had passed its peak and that all possible measures were being taken to prevent a recrudescence. The outbreak had been attributed to the presence of carriers of the virus in surroundings where, owing to Japanese neglect, unsanitary conditions favoured the spread of the disease. The incidence was mainly among young Chinese children. Cases occurring among Service personnel were believed to have originated from contact with carriers or cases among the civilian population.

Release of Doctors

On April 11 Mr. HECTOR HUGHES asked Mr. BEVAN whether the view which he expressed some months ago of reducing the number of doctors serving in the Forces to a ratio of about 2% of personnel had been achieved, and how many of the doctors so released since VE-Day were Scottish doctors who had returned to practise in Scotland. Mr. BEVAN replied that if Mr. Hughes had in mind the ratio of 2 per 1,000 referred to in Mr. Bevan's reply to Colonel Stoddart-Scott on Dec. 13, the answer was "Yes." The number of doctors released from the Forces since VE-Day included 926 who were recruited from

Scotland but it was not at present known how many of these had returned to practise in that country

Nursing and Domestic Staff of Hospitals

Mr JOHN MORRISON inquired on April 11 in which category of hospital—voluntary or municipal—the shortage of nurses was greater. Mr BEVAN said shortage of nurses was in general greater in the municipal hospitals, which included tuberculosis sanatoria and a large number of beds for the chronic sick.

Mr ISAACS announced on April 11 that the Government had decided to admit foreign women for domestic employment in hospitals. It was proposed to approach the Governments of a number of European countries with a view to extending to those countries a recruitment scheme now successfully operating with the assistance of the Belgian Government. In addition it would be open to hospitals to apply for permits for the admission of individual foreign women.

E.M.S. Service and the Defence Medal

Sir E. GRAHAM LITTLE asked on April 15 for what reasons the award of the Defence Medal was withheld from medical staffs who had given service in the Emergency Medical Service and other war work, while subordinate hospital servants such as theatre porters and mortuary attendants were eligible for the award. Mr ATTLEE replied that hospital officers and servants, other than nurses and midwives were not, as such, eligible for the award of the Defence Medal. It was granted to civilians primarily for civil defence service. Medical officers of the civil defence first aid services were eligible, subject to the approved conditions. If medical officers of hospitals, whether in the E.M.S. or otherwise were included, it would be difficult to exclude any qualified medical practitioners and it was hard to see where the line could be drawn.

General Medical Council

Sir HENRY MORRIS-JONES asked on April 18 whether Mr Herbert Morrison would consider reviewing the present constitution and powers of the General Medical Council in view of a recent decision of the High Court. Dr MORGAN, on the same date suggested legislation to reform the Medical Act of 1898 to give the General Medical Council a more democratic constitution, and especially to make provision for the hearing and investigation of unethical or unlawful charges against medical practitioners by an independent tribunal presided over by a judge. Dr MORGAN suggested, alternatively, the setting up of a Select Committee to review the functions of the present G.M.C. and consider any changes necessary in its constitution and procedure.

Mr EDE said he had been asked to reply. He understood that the G.M.C. itself appointed a committee in November, 1944 to consider the consolidation and amendment of the Medical Act. He assured Sir Henry and Dr Morgan that the whole position was being examined. The possibility of legislation at a suitable opportunity would be kept in mind.

Sir HENRY MORRIS-JONES said he made no reflection on the impartiality of the Council but asked if Mr Ede knew there was grave doubt about its competency to deal with the issues it had to decide. He asked Mr Ede to inquire into the possibility of strengthening it on the general practitioner side, over which class of doctor it has virtually the power of ruin on the uncorroborated evidence of neurotic women. Mr EDE said he would pass these observations to Mr Morrison.

Dr MORGAN asked whether it was right that the G.M.C., the body which needed reform, should be asked to reform itself. Was it not for the Government to see that errant doctors got justice according to the law? Mr EDE replied that self-reform was always a desirable occupation, but he would tell Mr Morrison that Dr Morgan thought a little stimulus from outside might assist. Mr HECTOR HUGHES said it was wrong in principle that the G.M.C. should be judge in its own cause and wreck the careers of people on inadequate evidence.

Dr MORGAN termed Mr Ede's reply unsatisfactory and gave notice that he would ballot to raise the subject on the adjournment.

Deafness in Children—Miss ELLEN WILKINSON states that she has no definite evidence of an increase in the incidence of deafness among children, but there appears to be a growing appreciation among parents of the importance of early diagnosis and treatment and increasing demand for special school education for the younger deaf children. There are 43 special schools for the deaf with accommodation for 4,230 children in England and Wales.

Notes in Brief

The number of civilian patients under care in mental institutions in England and Wales under the Lunacy and Mental Treatment Acts at the end of 1938 was 158,723 and, at the end of 1944, 146,268.

During the war years no case of yellow fever among British troops has been notified from Gibraltar or any other area.

Release by the Admiralty of the Physiology Department of University College Medical Faculty, and by the infection branch, Ministry of Food of the anatomy building of the same faculty, will take place in stages, beginning it is hoped, at the end of April.

A ration of 2 oz. of cooking fat, compared with the normal civilian ration of 1 oz., has been made available for persons suffering from tuberculosis whose condition entitles them to the special milk allowance.

During the three years 1943, 1944 and 1945, 184 prison or Borstal inmates were selected for psychiatric investigation. Of these, 24% were relieved or improved by treatment and are not known to have been reconvicted.

Mr Wilmot is not satisfied that the British x-ray industry can at the moment meet home and export requirements. To improve the position he has set up a committee to consult with the manufacturers on measures for the further development of the industry.

Vaccination and inoculation are not compulsory in the Merchant Navy, nor in the Royal Navy. Arrangements are made for merchant seamen to be informed of the danger of contracting smallpox and other diseases in foreign ports and for their vaccination and inoculation if they are willing.

Mr Bevan has stated in the House that the bovine tubercle bacillus is estimated to cause less than 2% of all cases of pulmonary tuberculosis, and about 30% of all forms of non-pulmonary tuberculosis, but it is not possible to give a separate figure for tuberculosis of the bones and joints.

It is estimated that at Dec. 31, 1945, there were in England and Wales approximately 182,000 persons under treatment for pulmonary tuberculosis and 54,000 for non-pulmonary tuberculosis, but no separate figures are available regarding non-pulmonary bone and joint cases.

Eleven cases of smallpox have been admitted this year to the Port Health Hospital New Ferry. Of these six were members of the Forces and one a member of the crew of a ship arriving at Liverpool.

Medical News

A Chadwick lecture on "The Rehabilitation of Displaced Persons and its Hygienic Bearings" will be given by Major Evre Carter at the Allin Hall, Palmer Street, Westminster, S.W., on Tuesday, May 7, at 2.30 p.m.

A meeting of the Medical Society of the L.C.C. Service will be held at the County Hall S.E., on Wednesday, May 8, at 2.30 p.m., when there will be a discussion on "The Treatment of Minor Injuries and Infections of the Hand," to be opened by Mr R. V. Lewys Lloyd, Mr J. C. Gillies, and Mr J. Gabe.

Dr A. S. Parkes, F.R.S. will read a paper on "Hormones" before the Royal Society of Arts, John Adam Street, Adelphi, W.C.2 on Wednesday, May 8 at 1.45 p.m.

Meetings of the Royal Sanitary Institute will be held at Ipswich Town Hall on Friday and Saturday, May 10 and 11. At 2.30 p.m. on May 10 papers will be read by Dr M. Markowe on "The National Health Service Bill" and by Mr J. B. Sorey on "The Use of Standard Concrete Housing for Temporary Hospital Buildings at Ipswich." At 10.30 a.m. on May 11 papers will be read by Dr S. M. Laird on "The Operation of Regulation 33B" and by Dr Dons E. P. Jolly on "The Adaptor Act."

The South Wales Children's Nutrition Council has arranged a conference on school meals (How to "Speed Up the Scheme") on Saturday, May 18 at 2.30 p.m., to be held at Engineers' Institute, Park Place, Cardiff. The discussion will be opened by Dr Greenwood Wilson, medical officer of health for Cardiff and Dr Evan Thomas, deputy medical officer of health for Glamorgan, with Mr Eddie Williams, B.Sc., in the chair. Delegates from all interested organizations are invited.

Recent advances in medicine will be the general subject of a course of lectures arranged by Prof. Pasteur Vallery Radot, to be held at the Hôpital Broussais, 96, Rue Didot, Paris, on May 17, 18, and 19. Endocrinology, pathology of the liver and kidneys, the sulphonamides, penicillin, blood transfusion and its problems and the treatment of burns are among some of the subjects to be covered. Further details may be obtained from the Scientific Office, French Embassy, 1, Carlton Gardens, London, S.W.1 (Tel. Whitehall 5444 Ext. 403), or Dr Jean Hamburger, 29, Boulevard de Courcelles, Paris 8.

The Harveian Society of London announces that the Harveian Lecture on "Progress of Aviation Medicine in the R.A.F. and its Application to Problems of Civil Aviation" will be delivered by Air Marshal Sir Harold Whittingham at the Royal College of Surgeons of England (Lincoln's Inn Fields, W.C.), on Monday, May 27, at 5 p.m.

The spring meeting of the British Orthopaedic Association will be held at the Royal Victoria Infirmary, Newcastle-upon-Tyne, on May 24 and 25.

A meeting of the directors of the Society for Relief of Widows and Orphans of Medical Men was held on April 10, with Dr. R. A. Young, president, in the chair. The death of a member, Dr. F. C. Kempster, who was elected in 1892, was reported; also the deaths of two of the widows in receipt of grants, of whom one had been on the funds since 1920 and had received from the Society £2,074, the other since 1934 and had received £982. The annual general meeting will be held on Wednesday, May 8, at 5 p.m. Any member who has been serving in H.M. Forces and who is now demobilized is asked to inform the secretary of his present address. Membership is open to any registered medical man who, at the time of his election, is residing within a twenty-mile radius of Charing Cross. Relief is granted only to the widows and orphans of deceased members. Full particulars may be obtained from the secretary of the society, 11, Chandos Street, Cavendish Square, W.1.

Three representatives of the Greek Ministry of Hygiene—Dr. Phoebus G. Copenaris, director-general; Dr. Stephopoulos, secretary; and Dr. Razi, chief of quarantine—have arrived in this country under the auspices of the British Council to study our health services. In co-operation with the Ministry of Health arrangements have been made for them to meet British authorities and to visit hospitals and other medical institutions.

Sir Alfred Webb-Johnson, P.R.C.S., has accepted the presidency of the Association of Certificated Blind Masseurs, which exists to safeguard the professional interests of blind chartered physiotherapists; and Dr. William Moodie has been appointed general consulting psychologist to the National Institute for the Blind.

The Central Midwives Board for England and Wales has re-elected Mr. Arnold Walker as chairman and Mr. J. P. Hedley as vice-chairman for the year ending March 31, 1947.

The next meeting of the Ophthalmological Society of Australia will be held in Melbourne in October, 1946.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* the notifications of measles increased by 284. Other infectious diseases declined: whooping-cough by 175, acute pneumonia 96, scarlet fever 26, and dysentery 24.

The increase in measles was confined to London and Lancashire, where there were 214 and 58 more cases than in the preceding week; the London notifications were 37% of the total for the country. Whooping-cough declined in most areas, except London and the south-eastern counties, where the cases rose from 351 to 393; the largest falls were Warwickshire 65 and Yorkshire West Riding 41. The total new cases of diphtheria remained unchanged, and the only local alteration of note was a fall of 10 in Warwickshire. There was a decline of 29 in the incidence of scarlet fever in Lancashire.

Dysentery notifications were fewer than in any previous week this year. No new outbreaks were notified. In Surrey 31 further cases were recorded, compared with 67 in the preceding week. Other large returns were Lancashire 43, London 26, Warwickshire 17, Leicestershire 14, Essex 11, Staffordshire 10.

In *Scotland* large decreases were recorded for acute primary pneumonia 87, and scarlet fever 61, while rises occurred in the incidence of whooping-cough 26, and diphtheria 11. Scarlet fever is now at the lowest level for recent months. The rise in diphtheria was in the Western Area, where the cases increased from 78 to 90. Zetland County, where no case was recorded in the preceding week, had 43 cases of whooping-cough.

In *Eire* notifications of diphtheria increased by 10; dysentery and diarrhoea in infants under 2 years of age increased in Dublin C.B. from 36 to 40.

In *Northern Ireland* the only appreciable change was a decrease of 12 in cases of scarlet fever.

Death from Smallpox

A soldier recently returned from the Far East and admitted to the Clayton Smallpox Hospital on April 21 died there on April 28. There has been no further case so far, and all known contacts are being kept under observation.

Week Ending April 20

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,051, whooping-cough 1,607, diphtheria 415, measles 2,392, acute pneumonia 652, cerebrospinal fever 64, dysentery 189, paratyphoid 9, typhoid 3. Three cases of smallpox were imported during the week.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended April 13

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable; no return available.

Disease	1946					1945 (Corresponding Week)

ANY QUESTIONS?

Epilepsy and Intercurrent Infections

Q.—Is there a biological antagonism between schizophrenia and epilepsy? Do epileptics undergo a remission of fits in varying degree while suffering from severe general infections particularly pneumonia? If so could the remission of fits during pneumonia be due to the altered respiratory rhythm? Would the induction of an artificial pneumothorax be of value in such cases?

A.—Chronic epileptics may show a lessened fit incidence during the acute phase of some intercurrent disorder of an infective nature. Measles is a good example, also pneumonia during the febrile stage. I know of no evidence to suggest that the alteration in the respiratory rhythm is responsible, or that artificial pneumothorax in epileptics would produce a relative or temporary remission. A condition of acidosis is usually regarded as the explanation of the temporary improvement in epileptics during infections. Of course, hyperventilation of the lungs (as from deliberate over-breathing) is known to aggravate the abnormal cortical rhythm of epileptics, and even at times to precipitate an attack. An antagonism between schizophrenia and epilepsy has certainly been claimed, but has also in all probability, been exaggerated.

Nocturnal Erections

Q.—Two male patients aged 48 and 50, one married and the other single, complain of being awakened at night by erections. There is no pain but an urgent desire to micturate. Both have clear, sterile, normal urine, blood urea normal, radiological and cystoscopic findings normal. Prostatic enlargement is not noticeable. Both confess to some sexual frustration. Is this a physical or a psychological condition? What further investigation and treatment do you recommend?

A.—Very little help can be given about these patients. Sometimes in single men psychological factors can be found which explain nocturnal erections. I have known cases in which they occurred only at night and by day the patient was impotent and without desire. But this would not apply to the two cases in question. They have been examined and the existence of a physical cause has been excluded. Possibly it might be helpful to examine prostatic fluid expressed by massage for the presence of pus cells. In any case, a course of prostatic massage might be a useful form of treatment. Small doses of luminal should be given before going to bed. But I have to admit that I have had several cases, but in more elderly men, who have suffered from this trouble, and who have not received benefit from any form of treatment. No explanation could be found for the condition, and I have regarded it as being a symptom of a "male climacteric."

Botryomycosis

Q.—What is the best treatment for botryomycosis?

A.—The term botryomycosis was used to describe an affection of the scrotum occurring in castrated horses and thought to be due to fungus. A similar type of lesion in man as the result of minor injury or infection in any site led to the term botryomycosis hominis being employed. Since Radcliffe Crocker's paper in 1903 (*Med Soc Trans Lond*, 26, 143), however, the term granuloma pyogenicum or infective haeman-

gioma has more commonly been employed. The lesion is no more than a small tumour of granulation tissue and is therefore highly vascularized.

The most effective treatment is to remove the tumour with a curette, using local anaesthesia, and cauterize the base—liquor hydrarg. nitratis acidus is useful for this purpose. Many authorities also give an application of x rays following this treatment—about 400 r units unfiltered, at 60 kV. The lesion will usually clear with x ray therapy alone, and occasionally will respond to sulphonamides by mouth and local antiseptic measures.

Carbon Monoxide Poisoning

Q.—Is there any evidence that inhalation of air polluted with carbon monoxide gradually and progressively kills the white blood corpuscles?

A.—There is no evidence that inhalation of carbon monoxide has any effect on the white blood corpuscles. The toxic action of carbon monoxide can be completely explained on the basis of chemical asphyxia. Carbon monoxide is not a cumulative poison and there is no such condition as chronic carbon monoxide poisoning. Daily exposure to small amounts of carbon monoxide may lead to a continuous mild carboxyhaemoglobinemia producing a partial deficiency of oxygen to which the body will respond in the usual way—i.e., typically by a mild polycythemia. There is no evidence that the white cells are involved in the process.

Contact Lenses for Myopia

Q.—What is your opinion of contact lenses for high myopia? What is the best solution to employ with the lenses? Are there any possible ill effects from their prolonged use?

A.—Contact lenses are useful in high myopia. The length of time the lenses can be tolerated by the eyes varies from one case to another. The least period of time for which they can be worn is usually four hours the most about eighteen hours. No ill effects result if the lenses are used intelligently and care is exercised in putting them in and removing them. In fact if one theory of the causation of myopia is correct they may have a beneficial effect. The best solution which has been so far discovered to use with the lenses is 2% sod. bic.

Boiling Coffee Twice

Q.—It is popularly supposed that boiling coffee again after it has been made changes its flavour or makes it bitter. Is this true? If so why?

A.—Boiling coffee again results in a loss of aroma and of certain volatile flavouring materials, and the underlying somewhat bitter flavour thus becomes more apparent. There is no increase in bitterness. At the same time there are certain oxidation changes which take place, and these also tend to change the flavour.

Dimethyl Phthalate and Artificial Silk

Q.—A note on dimethyl phthalate (D.M.P.) states (Jan 26 p 153) that it "dissolves certain types of artificial fabrics." What fabrics?

A.—The phthalates dissolve cellulose, nylon, polyvinyl chloride, methacrylates, polystyrene, neoprene, and Buna N. Materials made of these synthetic substances will be attacked—e.g. stockings or other underwear of "artificial silk," spectacle frames, fountain pens, buttons and some types of artificial jewellery.

Migration of Foreign Bodies

Q.—A patient ran a needle into her thumb in 1934 and half of it was recovered. Yesterday, when she was vomiting, the other half appeared in the vomit! I have examined both pieces and the second half fits exactly on to the first half. Is this remarkable or not?

A.—Numerous examples of the migration of foreign bodies in the tissues have been recorded. As in the present instance, some are well authenticated, and the phenomenon, although remarkable, does not appear to be very rare. Gould and Pyle (*Anomalies and Curiosities of Medicine*, New York, 1937) cite some strange cases, mostly dating from antiquity. Lambert

from Egypt he mentioned a mode practised by the Arabs. It was to approximate the edges of the wound with finger and thumb of one hand, and to induce as many as were necessary of the large strong-mandibled ants to be found in those parts to clip the edges together, holding the insect with the other finger and thumb. As soon as the jaws closed, the operator pulled off the rest of his able collaborator, leaving only its head holding on like grim death! In this ingenious manner as many ants were used as were required to close the incision neatly. There being no ants of the size required available in this happy isle I have never been able to prove the value of the procedure. It has often occurred to me that the Zoo authorities might be induced to furnish a supply of large ants for the treatment of incised wounds in "rheumatic" subjects, for more than one of my rheumatic patients have reported a freedom from their symptoms after a visit to Burnham Beeches, where they were treated, free gratis and for nothing, by the ants that there abound. I could think only of formic acid as an explanation. Do you think "there may be something in it"?

A Clean Shave

Dr. L. ERASMUS ELLIS writes from Durban, South Africa: In your issue for Dec. 29, 1945 (p. 923), you give a review of *Medical Uses of Soaps*, and in doing so you mention an assertion in the book that a dull razor causes less trauma to the skin than a sharp one. This I can fairly conclusively support by practical experience. For years I have adopted the plan of using a different razor blade, in a safety holder, every day of the week, having seven blades in commission. Using these blades only once a week, some of them last for months, but they all vary in the "finish" of their respective shaves. After shaving, I use a mildly antiseptic lotion containing a large proportion of spirit on the shaved surface. Applied to an ordinary skin surface this spirit lotion is cooling, but does not smart. On application to the newly shaved area of the skin, however, it tingles and sometimes smart considerably, and I notice that this reaction is much greater after using a new razor, which gives a much cleaner shave than one that has been used for some time, which produces a less smooth skin surface. The difference is quite remarkable, and brought home to me the considerable amount of trauma that we inflict upon the skin by shaving. This is all the more interesting to me personally, as I happen to be specializing in dermatology.

Aphthous Ulceration of Mouth

Dr. JOHN HALLAM (Liverpool) writes: With reference to the question and answer under the above heading (March 9, p. 379), I have seen between 20 and 30 cases of this painful condition in the past eighteen months. A considerable proportion of these attacks are either associated with, or follow, a mild gastro-intestinal disturbance. I have had 100% success in treating them with:

R Sodium thiosulphate (hyposulphite) .. 10 gr. (0.65 g.)
Tinct. card. co. 5 min. (0.3 ml.)
Aq. ad 1/2 oz. (15 ml.)
Sig: 1 2 oz. (15 ml.) i.d.s., p.c. Taken for one week.

I have been able to follow up about half the cases and have no record of any recurrence. I cannot agree with the indiscriminate use of penicillin lozenges or pastilles as you advocate. In fact, the buccal flora would, on clinical evidence of recurrence of oral infections originally treated with penicillin, have great power of becoming penicillin-fast. This has been so evident that I now use local penicillin only as a "boost" dose to a systemic course.

Sunflower Seeds

Mr. E. F. HURT writes: A question and answer on sunflower seeds (March 25, p. 455), discussed the possible therapeutic and nutrient value of this seed. To-day sunflower is considered one of the world's most important oilseed crops, the numerous varieties being capable of growth in almost any climate or soil. Its value lies partly in the oil (32 to 40%) and partly in its high protein content (about 55%). Up to 1939 the most important growing countries were Russia, with a production of some 3,000,000 tons of seed annually, Rumania, and the Argentine, while smaller quantities were produced in Hungary, Uruguay, India, Egypt, and even France and elsewhere. The oil is very largely used for the manufacture of margarines and vegetable lards, and was also most extensively used for cooking on the Continent as well as for canning sardines, etc. The seeds have long been considered a national food in Russia, and of more recent years have been dehulled and sold in packets in the U.S.A., in a similar manner to ground- or pea-nuts. But the most important advance is shown by the report in *Science* (U.S.A., April 27, 1945) on the findings of Prof. and Mrs. Harry G. Day, of Indiana University, in co-operation with Ezra Levin of Monticello, Ill. They found that sunflower seed was an important source of B vitamins, superior to wheat germ or corn germ and far superior to defatted soya-bean meal in this respect. Prof. H. H. Mitchell, of the University of Illinois, had already shown the protein in sunflower seed, after oil extraction, to be in the same class as oats, wheat, and barley, such

residue being nearly 50% protein. Similar solvent-extracted leave residue was also experimented on for human food, and a Dr. Levin report on the latter described it as a "palatable light-colored powder" which could be satisfactorily blended with white flour, etc., to make very appetizing baked goods. Since this report appeared commercial manufacture of protein foods from sunflower seed has commenced in the U.S.A., and Mitchell, Hamilton, and Bradley of the University of Illinois, point out, in the *Journal of Nutrition* (1945, 29, 13), that such protein was 94.3% digestible with a biovalue of 64.5%. By heat treatment, for low-temperature extraction of oil, the protein content was improved and was found to be higher than that of other foods such as soya-bean and coco-nut. A very recent report (Jan., 1946) from Canada shows the stress that the Canadian Ministry of Agriculture are putting on increased sunflower production in the prairie provinces this year. It is a pity that so little has been done commercially with sunflower in this country in the way of experimenting on its many uses, particularly during the war years when the crop was being developed here.

Trench Mouth

Dr. JACK FREEMAN (London, W.) writes: I feel that comment is called for on the reply to the inquiry "What is the best treatment for so-called trench mouth?" (March 16, p. 419). "Trench mouth" is acute ulcerative gingivitis, and I do not propose here to enter into the various signs, symptoms, and differential diagnosis. I would stress the aetiology and the simple means it offers for treatment. Briefly the organisms found in the lesion are spirochaetes and accompanying fusiform bacilli. These organisms can be isolated from most mouths, but it is only when conditions are such as to encourage their growth that the clinical picture develops. The prime condition is anaerobiosis, and this is accelerated by the accumulation of food or greasy particles around the necks of teeth and filling the interdental spaces. Hence the outbreaks among communal groups—e.g., the Services, factory canteens, etc.—where cooked fats are readily from stews and fatty gravies. First step in treatment is, therefore, the use of soap combined with the thorough rinsing of the oral cavity with 10% hydrogen peroxide to combat the anaerobes. The soap prepares the way, loosening the grease, lowering surface tension, and neutralizing acids. The oxygen is then liberated where it can do its work—i.e., in the depths of the interdental ulcers. The main aims of treatment are: (1) removal of stagnation areas and grease; (2) destruction of the harmful bacteria; (3) stimulation and keratinization of the mucous membrane.

Escharotics, such as chromic acid, should be avoided. One has little or no control of their activities. They deepen pockets and interfere with granulation. They are extremely painful in an already painful ulcer. The lesion is already acid in reaction, and an alkaline agent, soap, not only relieves pain but gives better results. With very acute cases coming into my surgery I use a spirochaetocidal N.A.B. or mapharside, sprinkled direct from ampoule to gingiv (infection is localized and not blood-borne, and injection technique is neither indicated nor necessarily effective), and massaged through closed lips, and finally worked gently into pockets with a blunt earler. Patient is dismissed with the most lucid instructions for soap and H₂O₂ therapy at home. Soap applied with tooth-brush or cotton wool, and thorough rinsing with H₂O₂.

This treatment gives 100% cure. All symptoms are gone inside twenty-four hours, and if the indicated home oral hygiene is efficiently carried out, ten days will see the ulcers healed and the mucous membrane firm in appearance. M. J. Glickman was the first to approach this infection correctly from the aetiological factor and his findings and conclusions should be more widely known. Other factors favouring the onset of the condition, such as malocclusion, misplaced teeth, incorrect fillings, badly fitting crowns, excessive tartar, etc., require the attention of the dental surgeon. Avitaminosis, general debility, mouth-breathing, and all other conditions leading to a preliminary gingivitis need the attention and assistance of the physician, and the co-operation of both on the right lines is the ideal.

Naples Typhus Epidemic: Correction

Lieut.-Col. H. J. CRAFTURD-BENSON writes: In my article published in the *Journal* of April 13 (p. 579) entitled "Naples Typhus Epidemic 1942-3" I regret that there has been a mistake in the date. The epidemic referred to was, of course, 1943-4. Naples was not occupied by Allied Forces until September, 1943. I apologise to you and your readers for the error.

Disclaimer

Dr. J. TUDOR LEWIS, Medical Officer of Health, Barnsley, wishes to be known that recent references to him in the daily press were inserted without his permission or knowledge.

We learn that Lieut.-Col. Gopal S. Chawla, hon. secretary of the Punjab Branch of the B.M.A., has received the title of Sarder Bahadur among the Indian honours recently conferred.

ECONOMIC STATUS AND THE HAEMOGLOBIN LEVEL OF CHILDREN OF MEN IN THE FIGHTING SERVICES AND OF CIVILIANS

BY

HELEN M. M. MACKAY, M.D., F.R.C.P.

Member of the Staff of the Medical Research Council

LUCY WILLS, M.A., M.B., B.S.

Pathologist to the Royal Free Hospital

AND

KATHLIN BINGHAM

Assistant, Pathological Department, Royal Free Hospital

The Committee on Haemoglobin Surveys of the Medical Research Council (1945) has stated categorically that "it has been clearly shown in the past that haemoglobin levels vary with family income" (Spence, 1934; Fullerton, 1936; Ross and Summerfeldt, 1936; Reid and Mackintosh, 1937; McCance *et al.*, 1938; Yudkin, 1944a). The lower haemoglobin level associated with a lower economic status may have multiple causes, but McCance and his colleagues (1938) have demonstrated a close correlation between income, adequacy of the diet, and haemoglobin level.

The object of this investigation was, first, to compare the haemoglobin level of children of men in the Forces and of civilians; and, secondly, to study whether the composition of the household or evacuation of the children affected this level.

Clinical Material and Technique

Just under 500 children, aged 4 to 14, were examined in December, 1944, at a county council school in an urban district in Surrey. This school was chosen because, being near a military depot, nearly half of the pupils were children of men in the Forces. The teachers recorded for us on each child's card the parents' occupations, the composition of the household, the total number of siblings, with information as to evacuation and the consumption of dinners or milk in school. There were 264 children of civilians among the 493 examined. Their fathers' occupations are shown in Table I. About 65% of the total were

account of the flying-bomb attacks and evacuation of children, so that when the examination was carried out many of the children had recently returned from evacuation.

Estimations were made by the Haldane method, and figures are given with the National Physical Laboratory B.S.I. corrections applied for colour tubes and pipettes, together with a mean correction for the diluting tubes. Each observer used 8 diluting tubes in strict rotation, and the N.P.L. corrections for each group of 8 were almost identical with each of the other two groups. The maximum individual correction on any one diluting tube neglected by using a mean correction was -0.9 at 80%. The children were grouped by age, and each observer estimated approximately one-third of the children of each year of age. Each child warmed a hand in hot water just before the estimation and the blood was taken from a prick in the thumb.

Difference in Colour-matching Between the Three Observers

Three colour tubes were used in this survey—one by each observer. It was found that K. B. fairly consistently matched at a lower level, L. W. at an intermediate level, and H. M. M. M. at a higher level (see Table II). L. W.'s mean and H. M. M. M.'s

TABLE II—Mean Haemoglobin Level at each Year of Age: Results of Each Observer

in one or other of the following categories: artisan, male nurse, general or agricultural labourer. Many of the mothers were working outside their own homes, and some were in full-time employment—for example, as nurses in the neighbouring mental hospital. The investigation was originally planned for the spring of 1944, but had to be postponed until the end of the year on

mean were higher by 3.0 and 5.1 respectively than K. B.'s. When the differences between the mean values of the three observers in December, 1944 (present survey), were compared with the differences between the means of the same three observers in the summer of 1943 (Committee on Haemoglobin Surveys, Medical Research Council, 1945, p. 67) it was found

that though the difference in colour-matching between H. M. M. M. and L. W. had remained approximately unchanged, the difference between K. B. and the other two observers had increased. It seems probable that this was in part due to the actual colour tubes used, in spite of the fact that the N.P.L. correction was applied in each case; for in yet another investigation carried out by H. M. M. M. and K. B., when one and the same colour tube was regularly used by both observers, it was found that the difference in colour-matching between these two was only about 1% as late as the summer of 1945. The differences in colour-matching of the observers, in the present survey are taken into account in the analysis of the figures.

Analysis of Results

Haemoglobin Level in Relation to Age.—The mean haemoglobin level was 85.4 at 5 years of age, and there was a steady rise to 91.9 at 13 years (Table III). At 7 to 11 years the values

TABLE III.—Mean Haemoglobin Level by Age: "Forces Children" and "Civilian Children" in Present Series Compared with Other Series

Age in Years	Present Series, 1944						Series of 1942-3		M.R.C. Survey, 1943

13	91.9	58	92.2	13	91.8	42	—	—	97.1	223	94.3	134

are similar to or slightly lower than those obtained at two other county council schools in 1942 and 1943 by two of us with R. H. Dobbs (Dobbs *et al.*, 1944). At each age from 5 to 13 years they are slightly lower than those of the corresponding age groups in the Medical Research Council Haemoglobin Survey (1945) carried out in 1943. In view of the alteration in

teachers as a school unit. The duration of evacuation varied greatly, but children who had been evacuated with their teachers had for the most part remained away until shortly before the date of this investigation. Since the great majority of those evacuated with their teachers were 10 years of age and over, a simple comparison of mean haemoglobin values of those remaining at home or evacuated with the school is invalidated by the difference in age. For this reason the observed mean value of each group is compared with the expected mean, taking into account both the age composition of the group and the observer carrying out each estimation. The figures from which the expected mean has been calculated are given in Table II, which sets forth the observed mean haemoglobin value obtained by each observer at each age. The difference between the observed mean and the expected mean for children of all ages not evacuated, children privately evacuated, and children evacuated with their school was under 1% (Table IV).

TABLE IV.—Mean Haemoglobin Level of Children who were Evacuated and of Children who Remained at Home

	Not Evacuated	Privately Evacuated	Evacuated with Teacher
No. of children	187	183	62
Observed mean Hb	88.3	88.8	88.6
Expected mean Hb	87.7	89.7	89.0
Difference of observed from expected mean	+0.6	-0.9	-0.4

Effect on the Haemoglobin Level of Economic Status as indicated by Number of Wage-earners and Number of Dependent Children.—Under the existent conditions of shortage of man-power and shortage of housing there were in many households earners other than the parents, whose presence had an important bearing on the financial resources of the household. These earners might be older children, grandparents, aunts, cousins, etc. In order to obtain a comparison of haemoglobin levels of children in households with larger and smaller incomes per head as determined by the composition of the household, the children have been allocated to different subgroups. The first group was one in which the mean income per head was likely to be considerably above the average: in this group were placed children from households in which there were not more than two dependent children together with three or more wage-

K.B.'s matching level in the present investigation, and the small numbers involved, it is possible that the real differences in haemoglobin level between the children examined in the Medical Research Council Survey and the present one were smaller than the figures suggest.

Effect of Evacuation on the Haemoglobin Level.—About half the children under 10 years old had been evacuated—the great majority privately, and many with their mothers. Nearly three out of four of the children aged 10 to 14 years had been evacuated, and of this evacuated group about one-third went with their

earners—e.g., the father, who might or might not be resident in the home; and two other wage-earners, one of whom might be the mother. The other subgroups consisted of children from households where there were no wage-earners other than the parents and where the dependent children numbered respectively (a) 1 or 2; (b) 3; and (c) 4 or more (Table V). Since some of the children did not fall into any of these subgroups the number shown in Table V falls short of the total examined. As before, the difference of each observed mean haemoglobin value from the expected mean has been calculated to allow

both for the effect of age and for the differing levels of colour-matching of the three observers. Table V shows the results.

There is a progressive fall in the observed mean haemoglobin level between the first subgroup and the last. Moreover, the differences between the expected means and the observed means also fall into sequence. Children of households with three or more earners and only one or two dependent children have the highest mean haemoglobin (1.4 over the expected mean); the children of households where the parents are the only earners and there are four or more dependent children have the lowest mean haemoglobin (1.4 under the expected mean); and those children whose parents have one and two or three dependent children are intermediate in the series. As evacuation was likely to have smoothed out differences due to differing home circumstances, Table V shows also results when the children of 10 years old and upwards (three-quarters of whom had been evacuated) are excluded. This smaller group shows a greater difference between the various subsections: 3.2 over the expected mean for the first subsection, and 2.1 under the expected mean for the last, or a difference of 5.3 between children living in the better-to-do households and those in families with four or more dependent children. Two other groupings are shown—children of Service men and children of civilians, with similar gradations in haemoglobin level. The unbroken sequences in haemoglobin level in all the different groupings of children shown in Table V are striking. In the last column of Table V are given the differences in mean haemoglobin level between the first subsections and the last—i.e., between the children of better-to-do households and those of families with four or more dependent children, in each series. The differences in the four series—(a), (b), (c), and (d)—vary between 5.3 and 2.6, and the first three are statistically significant. Thus in spite of the complicating factor of the evacuation, there is shown to be a strong correlation of haemoglobin level with the number of the dependent children. These findings tally closely with the results obtained at another county council school in 1943 (Dobbs, Mackay and Bingham, 1944) and correspond with Yudkin's findings (1944b) for elementary-school children in Cambridge.

Haemoglobin Level of Children of Men in H.M. Forces compared with that of Children of Civilians.—The mean haemoglobin level of children whose fathers were in the Forces was slightly lower than that of children of civilians at each year of age from 5 to 9 years inclusive (Table III). From 10 to 13 years there was no consistent difference, but from 10 years of age upwards nearly three out of every four children had been recently evacuated from their homes, so that differences in haemoglobin level due to their own home conditions would probably have been obliterated by evacuation. The difference between "Forces children" and "civilian children" shows itself in various groupings of the figures: (a) When the whole series are grouped by age it is apparent at each year of age up to 9 years (Table III). (b) When the series are grouped according to the observer estimating the haemoglobin it is apparent in each subgroup (Table VI). (c) If the children of civilians

VII). Since in all these groupings or subdivisions the "Forces children" have a lower mean value it is certain that the difference is a real one and has not arisen by chance.

Discussion

It is well known that the standard of living of children in the social class to which the children in this school belonged was much higher in 1944 than it was in the pre-war years, as a result of full employment and higher wages, together with some food priorities for school-children in wartime. Yet, even with this higher standard of living, families with only the parents earning were handicapped in health, as indicated by their lower mean haemoglobin level, when compared with children in households with three or more earners. This handicap increased with the number of dependent children in the family. There was a lowering of the mean haemoglobin level of the children in the larger families by 5% in comparison with children attending the same school but coming from families with more wage-earners and fewer dependent children (Table V). Moreover, in spite of progressive and much-needed improvements in the family allowances for men in the Forces, their children were still, at the end of 1944, handicapped as compared with "civilian" children, whether coming from small or large families. Though a 5% difference in mean haemoglobin level may seem small, yet, by analogy with younger children, we believe that a lowering of haemoglobin level in school-children by this amount is likely to result in a rise in morbidity rate (Mackay, Bingham, and Dobbs, awaiting publication), and this is the reason why a difference in haemoglobin level of this order is a matter of importance.

Since the country must continue to maintain a considerable standing Army as well as a Navy and an Air Force, it is essential that the nation should see that the service of men in the Forces is not performed at the expense of the well-being of their families.

Unless the problem of the economic handicap of large families can be solved at least to the extent of ensuring that an increase in the number of children does not mean an inadequate diet for the family, the birth rate, except among the improvident, is unlikely to rise.

Summary

A series of 493 children aged 4 to 14 years were examined in December, 1944, at a county council school in a town in Surrey. Previous evacuation of the children had little effect on the mean haemoglobin level. When the proportion of wage-earners in the household was high the mean haemoglobin level of the children was also relatively high; when the number of dependent children increased the haemoglobin dropped correspondingly: findings which confirm those of an investigation undertaken earlier in the war. Children of men in the fighting Services had a lower mean haemoglobin level than the children of civilians at all ages under 10 years, after which home influence on the haemoglobin level was masked by evacuation. There was a similar difference in haemoglobin level between "Forces children" and "civilian children" when results were analysed to show the effect of increasing numbers of dependent children. We have no evidence as to the optimum or normal mean haemoglobin level for school-children, but the lowered haemoglobin level in "Forces children" and among the

TABLE VI.—Mean Haemoglobin Levels as obtained by Each of the Three Observers; "Forces Children" and "Civilian Children"

Observer	All Children		"Forces Children"		"Civilian Children"

and of men in the Forces are separately grouped to show levels in households of three or more earners as well as in families of increasing numbers of children, the results are similar for "Forces children" and "civilian children," but in each subsection the children of Service men have a slightly lower mean haemoglobin level than the children of civilians (Table V). (d) When the individual values at different ages obtained for "Forces children" and "civilian children" are ranged in order to show their frequency distribution, the frequency of lower values is greater in each subsection of "Forces children" than in the corresponding subsection of "civilian children" (Table

children belonging to larger families reflects, we believe, an inadequate standard of living among at least a proportion of those composing these groups.

Our grateful thanks are due to the teachers, particularly to the heads of the three sections of the school—Mr. J. A. Richardson, Mr. H. S. Jones, and Miss G. Ellis—for their generous co-operation in this investigation with all the extra work it threw upon them. We are indebted to the Medical Officer of Health for Surrey, Dr. J. Ferguson, for permission to carry out the work, to the medical students and others who gave up several days to assist us, and to Dr. W. J. Martin for advice on statistical methods.

WEIL'S DISEASE OCCURRENCE AMONG WORKERS IN WELSH AND SCOTTISH COAL-MINES

BY

T. H. JENKINS, M.B., B.S., B.Sc.

AND

Wm. C. SHARP, M.B., Ch.B., D.P.H.

Regional Mines Medical Officers in Wales and Scotland (Ministry of Fuel and Power)

During recent years numerous articles have been published on Weil's disease (synonyms—spirochaetal jaundice, acute infective jaundice, leptospiral jaundice, spirochaetosis ictero-haemorrhagica, and possibly Nanukayami or 7-day fever of Japan, and slime fever of Eastern and Central Europe). The present paper is the result of inquiries conducted during the past few years into its incidence among mine workers in the Scottish and South Wales coalfields. Cases of Weil's disease among miners occurring during the past three years have been followed from mine to home or hospital into convalescence and return to work. During the past year a number of miners suffering from the disease have been treated with penicillin with most promising results. In this paper the incidence and prevention of the disease are dealt with, and the features referred to are mainly those peculiar or of special interest to coal-mining.

From April 1, 1940, infection by *Leptospira ictero-haemorrhagiae* has been included, subject to special conditions, in the schedule of industrial diseases under the Workmen's Compensation Act. Since man is usually infected through the medium of water or slime in or from places infested by rats, as mines, sewers, fish-cleaning premises, piggeries, farm middens, and slaughterhouses, and since infection may also occur from bathing in polluted water, no special process or work was included in the Order. It therefore rests with the worker to show that the disease was contracted in the course of his or her employment.

The disease has varied in name since it was first described. "Weil's disease" and "spirochaetal jaundice" remain in common usage although the Departmental Committee on Industrial Diseases recommended in its Third Report (1936) that these terms should not be used synonymously for infection by *L. ictero-haemorrhagiae* on the grounds that the illness may not in all cases be due to infection by that particular organism and that infection may occur without producing jaundice.

The disease is notifiable in Scotland but not in England and Wales. In British coal-mining the main events in chronological order are as follows. 1923: Buchanan and Gullard recognized and established the occurrence of spirochaetal jaundice among East Lothian miners. 1924: Spirochaetal jaundice became notifiable as an infectious disease in Scotland. 1933: Attention of Mines Department first drawn to cases occurring among Welsh coal-miners. 1940: Scheduled as an industrial disease.

Incidence

The following figures and tables show the prominent part played by certain Scottish and Welsh coal-mines in the epidemiology of the disease.

Scotland.—According to the annual returns, the numbers of cases notified since 1924, when the disease became notifiable, are as follows:

1924	1925	1926	1927	1928	1929	1930	1931	1932	1933	1934	1935	1936	1937	1938	1939	1940	1941	1942	1943	1944	1945
19	52	27	73	33	21	67	22	34	23	32	24	57	41	48	25	25	33	50	45	5	5

The returns do not indicate the occupational groups affected, nor do they state whether the diagnosis was confirmed. In 1934 Smith (Aberdeen) introduced Schüffner's agglutination test, which is highly specific. The incidence of known confirmed cases among Scottish mine-workers is as follows:

Year	Fatal	Non-fatal	Year	Fatal	Non-fatal
1924	..	2	1942	..	2
1932	..	3	1943	..	3
1934	..	1	1944	..	1
1936-7	..	7	1945	..	2
1938	..	1			
1939-41	..	5			22
					30

South Wales.—Gardner* between 1939 and February, 1943, examined 385 sera from patients all over Great Britain suspected suffering from Weil's disease. Altogether 58 cases gave positive reactions, and 21 of these were from South Wales (Carmarthen Glamorgan 8, and Monmouthshire 3, mainly coal-miners). The following cases have been reported as occurring among mine workers:

Year	Fatal	Non-fatal	Year	Fatal	Non-fatal
1933-5	..	1	1943	..	1
1937	..	1	1944	..	2
1939	..	1	1945	..	1
1940	..	2			11
1941	..	1			36
1942	..	3			

In all the cases noted above as occurring after 1935 the diagnosis was confirmed by serological and/or bacteriological examination. There is now a greater awareness of the disease, and since its inclusion in the industrial diseases in 1940 no case is certified unless confirmed by serological examination.

Mine-workers in Scotland and Wales formed a high proportion of the confirmed cases, fatal and non-fatal, occurring each year. These confirmed cases, Gardner states, may represent only a fraction of the infections actually occurring. Jaundice is usually present before the disease is suspected. According to Schüffner, jaundice is present in only 60% of cases. To quote Gardner: "It would be well if doctors dealing with patients exposed to the special risks by occupation or accident would have a serum test done in febrile cases developing headache, muscular pains, conjunctivitis, and intestinal irritation, without waiting for jaundice to develop."

In the table opposite the incidence in mines of known risk is listed together with certain pertinent data for each mine.

In Scotland and South Wales the mines concerned are drifts, levels, or slants, or if pits (i.e. having shafts) there are one or more connexions to slants. Each mine is known to have been infested with rats to varying degrees at the time of occurrence of the disease. The underground workings are wet over long portions, and collections of water (pools) are frequent. Horses or ponies are employed underground in all the Welsh mines concerned and in the two Scottish mines which show the highest incidence of cases. The regulations under the Coal Mines Act require in effect that horse-feed and water should be taken inbye when horses or ponies are employed underground.

All the recorded cases in mines occurred among underground workers except for one surface worker in Scotland who may have paid visits a little way inbye. Cases have occurred in practically all grades of underground employment.

Seasonal Incidence.—The numbers of cases recorded are insufficient for assessing a causal seasonal factor. There may be a slight relationship between the seasonal variation in the

* Bulletin of the Emergency Public Health Laboratory Service, May, 1943.

occurrence of the disease and the breeding of rats. If there is a seasonal influx of rats to mines with the onset of winter it would seem that certain conditions are required before clinically recognizable human infection can ordinarily occur, as most cases of infection appear from spring onwards.

Underground Environment

The mines of known risk are what are commonly called day drifts, slants, or levels, and lead direct from the surface into the mine workings. The actual coal face may be from 800

drawn traffic by subsidiary rope haulages. Stables are generally maintained underground.

Water from the surface, underground streams, or old workings forms scattered pools along the roadways and workings. Gutters or channels are made along the side of the levels or slants, and the water is thus directed to a central sump or reservoir, from which it is pumped to the surface. It is, however, often impossible to prevent shallow pools forming in the depressions and undulations along the mine roadway. Water is thus splashed about the sides of the roadway during

* An ostler who worked in the underground stables.

to 3,000 yards or more inbye. Double partings, or passbys, are formed at convenient points inbye, and serve as distributing and collecting centres. Horses or ponies bring along the coal-tubs from the working face to the double parting, where a journey, or rake of full tubs, is formed and brought to the surface by rope haulage. Many mines have replaced horse-

the passage of horse-drawn traffic and men. Slime and fungal growths in which the organism has been cultivated are often seen on the roof and timber supports. Water droppings from the roof are frequent. Under very wet conditions the men may wear oilskins and gum-boots but dispense with them in the drier parts of the mine.

The day's stock of horse-feed is sent down in sacks to the feeding-points, usually at or near the double partings, where it is emptied into large bowls. Practice, however, varies, and the horses may feed from nose-bags. Spillage is common, and it is usual to find the greatest number of "worked holes," and thus rats, near the feeding-points. Cuts and minor abrasions are a fairly common occurrence underground. Prompt first-aid attention is generally available if required.

There is extensive cover available underground for rats in the goafs (gobs and wastes). The only limiting factors in the distribution of rats in mines are deficiencies in food supply, movement of traffic, and the coal face itself. It appears that rats are attracted to the mine by the horse-feed. The slant or level provides easy access. The extensive cover, mine temperature, wetness, and darkness provide a favourable environment.

Rats

The main carrier of the *Leptospira* is the sewer-rat, *Rattus norvegicus*, and, far less commonly, the black rat, *Rattus rattus*.

Fecundity.—The female is fertile at three months. Oestrus, which lasts for three weeks, occurs every six weeks. Gestation lasts about 22 days. In a year six to eight litters are normally produced. The maximum life of the rat is about two years. A single pair of rats may in one year give rise to progeny numbering 600 or more. Rats are cannibals, and mortality among them is very high.

Breeding.—Under very favourable conditions breeding may take place throughout the year. Under ordinary conditions little occurs during winter months. The peak period is from early March to the end of May, with a lesser peak about the end of August.

Reinfestation.—Experience in factories and warehouses has hitherto shown that reinfestation occurs in roughly ten weeks after extermination has been effected.

Distribution of Rats in Mines.—There is little agreement regarding migration of rats into or from the mines. Some observers state that the rat colonies apparent underground maintain fairly level numbers and that migration is not noticeable. Others take the view that there is migration to the mines with the onset of winter, particularly if they are convenient to rivers, canals, or other waterways. The rats gain access to the mine workings by slants or slopes (surface mines) or via horse-feed. Horse-feed and scraps of bread thrown away by workers are the main sources of food for rats. Men generally carry their food in tin containers, but the practice is not entirely a universal one; even if it were it is often discounted by the unfortunate habit of throwing crusts and other scraps of food away. Human and horse excreta may also form part of the rat diet. Traces of rats in mines are somewhat different from those found in surface buildings or in the open. Often everything is wet and there are no smears. Droppings are often rapidly covered and obscured in the main roadways, and in disused roads are soon coated with fungal growth. Used rat places are polished and worn. These are the main traces. It is said that rats and mice do not coexist in the mine, although exceptions are instanced. It has also been recorded that in a mine where the only access was via the shaft the rats soon exterminated themselves when horses were replaced underground by mechanical haulage.

Preventive Measures

The prevention of Weil's disease in mines of known risk requires the co-operation of the men and the management. Some of the preventive measures are of a specialized nature and will be referred to only briefly. We are of the opinion that the first measures should be: (1) extermination of rats; (2) prevention of reinfestation; (3) rendering all food inaccessible. Further measures to implement the above are: (4) drainage of water and/or rendering stagnant pools unsuitable for the organisms; (5) use of protective clothing; (6) prompt and effective use of first-aid arrangements; (7) pit-head baths.

1. **Extermination of Rats.**—This requires to be intensive, and for this purpose the surface and underground workings should be considered as a single entity. In 1944 the Rat Infestation Branch of the Ministry of Food undertook, with a high degree of success, the extermination of rats in one of the

Welsh mines of known risk. Similar treatment of a Scottish mine took place in 1945. This occasion was correlated to extensive surface measures. It is estimated that the rats killed on this occasion numbered: surface, 315; underground, 215. The measure adopted is briefly:

A plan of the mine is inspected and a thorough survey for traces of rats made. The mine is divided into appropriate working sections. A system of pre-baiting with poisoned baits (arsenic or barium carbonate) and post-baiting is adopted. A test for reinfestation is made a month later. Where sections are continuous, special treatment of the overlapping area is called for. Full details of the planning, standard procedure, organization of the squads, and safety precautions are contained in the memorandum on Instructions in Poisoning Rats in Pits and Levels, issued by the Rat Infestation Branch of the Ministry of Food.

In one mine the manager reports that during a holiday period a few years ago, when horses were all taken to the surface, poisoned biscuits were laid down intensively, with good results. No rats have since been seen. At two mines the use of horses underground was discontinued. Rats, formerly rampant, ceased to be noticed anywhere underground within a few months and had not reappeared. This was attributed to starvation plus cannibalism. Even if these reports should be accurate it does not necessarily follow that haphazard methods are as efficient as carefully controlled methods.

2. **Prevention of Reinfestation.**—The proofing of main levels or drifts against rat movement is virtually impossible owing to the requirements of haulage traffic. Old roadways and airways may be effectively sealed against rats by suitable doors, which may be solid or of suitable stout mesh construction. This would depend on the requirements of ventilation. These physical deterrents, however, will not suffice where food is made available underground.

3. **Rendering Food Sources Inaccessible.**—(a) Horse-feed: Underground storage should be in steel bins with close-fitting lids. One mine has for this purpose a brick cabin with concrete floor and an accurately fitting door of steel plate. The regulations under the Coal Mines Act require in effect that horse-feed should be taken inbye where horses are employed. As stated previously, the replacement of horse traffic by mechanical haulage results in marked diminution in the rats seen. (b) Workmen should all carry food in metal boxes and should desist from throwing away crusts. (c) Full use of chemical conveniences, and their importance, should be stressed. (d) Restriction of the number of horse-feeding points would simplify the disposal of horse excreta.

4. **Drainage of Water and/or Chemical Treatment of Stagnant Pools.**—Where there is a definite incline drainage by narrow channels to lodgments is to be commended. From these lodgments there should be ultimate pumping to the surface. Level or undulating conditions tend to promote areas of stagnant water. Where such pools are unavoidable, acidification of the water will produce conditions inimical to the viability of the organism. Scottish authorities have recommended the liberal application of lime and/or chloros to roadways, etc., and are of the opinion that this gives satisfactory results. It is difficult to determine just how accurately the treatment is pursued and therefore to what extent it is effective. As in the case of horse-feed, water for horses or for any other purposes requires to be protected adequately from contamination.

5. **Protective Clothing.**—The main practical measure in this regard is the use of gum-boots. This is particularly important where, as often happens in wet mines, workers may be exposed to prolonged or repeated wettings in traversing certain stretches of roadways. In some cases gum-boots are worn to get through such places, and under drier conditions at the coal face the worker changes to ordinary boots.

6. **First-aid Measures.**—Where there is a known risk first-aid treatment should be given for even minor scratches and abrasions. In two recent cases there was a history of a cut on the hand (7 and 14 days respectively) before the onset of symptoms of Weil's disease. In both cases some time had elapsed before the wound received attention. It is believed that these wounds provided the means of entry of the organism.

7. **Pit-head Baths.**—These provide a general hygienic measure, and their use should be encouraged to the fullest extent. Although baths have been provided at a great many collieries for some years now, a few men do not use them. As a further

measure the washing of hands before eating should be urged. This does not seem easily feasible in the case of underground workers, but it ought not to be impossible.

Present Position and Observations

In general the occurrence of Weil's disease is for all practical purposes confined to mines which have direct access from the surface by levels, drifts, or slants, which are generally wet, and which are infested with rats. In South Wales horses are employed and feed is taken inbye in all cases. In Scotland horses are in use in only two of the mines concerned, but these two have the highest incidence of infection continuous over a period of years. The geographical distribution of cases is widespread in both regions, and several recent cases occurring at mines widely separated were the first to be recorded among miners in these areas. Most Scottish cases have, however, occurred within a comparatively small area. Within this same area there are several mines each employing some hundreds of men below ground—mines which have horses with stables below ground and are known to be rat-infested, but which to date are not known to have had a recorded case of Weil's disease.

The occurrence of a case, particularly of a fatal one, usually leads to intensive rat-extermination measures being undertaken for a time at least. This no doubt partly accounts for the sporadic nature of the incidence. The recent success of the Rat Infestation Branches of the Ministry of Food and of the Department of Agriculture in Scotland suggests that much can be done in rat extermination, but any underground efforts in this respect require to be co-ordinated with extensive surface measures. Periods when horses are withdrawn to the surface would seem to be the most suitable, since food for rats will then be at a minimum and poisoned bait will be more likely to be taken. The probability is that the disease is much more widespread than recorded cases indicate. It is rarely diagnosed without jaundice having appeared, and the high rate of mortality justifies the most energetic measures that can be taken to clear mines of rats and keep them clear. In South Wales intensive measures are being undertaken at the mines of known risk. From each of the mines concerned one or two men were selected to undertake a course in the methods of rat extermination adopted by the Ministry of Food. It is hoped that this will result in a marked diminution in the appearance of new cases of Weil's disease.

Certain questions remain unanswered. Among these are: What conditions favour increased virulence or attenuation of the organism? What is the viability of the organism in pit water and slime? Are rats infected *de novo* from such water and slime, or directly or indirectly from other rats? Is there a proper seasonal variation in the incidence or is it related to breeding?

All but one of the cases recorded were among underground workers. In nearly all of them the conditions of work were wet or necessitated traversing wet places. Cuts and abrasions are commoner underground and so facilitate the entry of the organism into the body; moreover, first-aid attention is more difficult than at the surface.

Glossary of Mining Terms

- Coal face** : The place where coal is hewn and filled.
Drift : A roadway, usually inclined, driven in stone from the surface to the workings.
Goad (gob or waste) : The area from which the coal seam has been extracted, partly or completely filled with debris.
Inbye : In a direction towards the working face and away from the outlet; the reverse of outbye.
Level : A roadway so driven in a particular stratum as to maintain a level course.
Outbye : In a direction away from the working face towards the shaft or outlet; the reverse of inbye.
Slant, slope : See Drift.

Summary

Cases of leptospiral jaundice occur among Scottish and South Wales mine-workers with such regularity and such a high mortality rate as to make the disease a definite occupational risk in certain types of mines.

The mines known to be concerned are all wet and infested with rats, and form a small proportion of the number of colliery undertakings in both regions. Rats gain access to the workings via levels, drifts, or slants, and possibly with horse-feed in course of transit.

In most cases live rats caught in the mines have been proved to harbour the *Leptospira*, which has also been isolated from specimens of pit water and slime.

Unless circumstances provide a guide there is every possibility that the disease may be mistaken for other conditions, particularly in the early stages. Proof is by positive agglutination reactions in ascending titres.

Facilities for laboratory diagnosis and hospital treatment are available and adequate in both the Scottish and the South Wales coalfields.

Approximately 33% of the recorded cases were fatal. Two to three months is the usual period of illness. One attack confers immunity.

Determined efforts at rat extermination are of primary importance, and should be so co-ordinated as to deal with surface and underground problems simultaneously.

We are grateful to many persons and bodies whose kind co-operation and advice have greatly facilitated the investigation and the compilation of this report. In particular we would mention Dr. S. W. Fisher, Chief Mines Medical Officer, who initiated the investigation and helped us in our labours throughout. We are also indebted to the Mines Inspectorate and to the Rat Infestation Branches of the Ministry of Food and of the Department of Agriculture for Scotland for guidance on the environmental aspects. Our thanks are again due to several medical officers in our respective regions for the notification of cases and advice on the medical aspects of the disease.

INSULIN SHOCK TREATMENT OF BRONCHIAL ASTHMA

BY

Z. GODLOWSKI, M.D.

*Physiopathology Department of the Polish Medical School and
Paderewski Memorial Hospital, Edinburgh*

Insulin shock was first introduced into the treatment of bronchial asthma by Wegierko in 1935; his later report on this subject (Wegierko, 1937) revealed very promising results, as he was able to remove the symptoms of asthma permanently or to mitigate them considerably for many months or even years. He thought (Wegierko, 1937) that the mechanism of insulin shock in the treatment of bronchial asthma lay in a violent stimulation of the whole vagal system, leading consequently to relaxation of the total smooth musculature of the body, including the spasmodically contracted bronchioles in these cases. He thus recommended insulin shock treatment for all conditions connected with spasmodic pains, such as nephrolithiasis, cholelithiasis, migraine, etc. He based his explanation on the fact that, in his observations, some of the cases in the early stages of insulin shock showed a slight fall of blood pressure, bradycardia, hot flushes, etc.—all symptoms described as due to vagal irritation; in the same stage of insulin shock patients began to feel a notable relief of breathlessness. It should however, be borne in mind that the vagal fibres of the bronchial plexus bring to the bronchial muscles a constrictory stimulus. Thus either the toxic doses of insulin produce a paralysing effect on the vagal system and thus cause relaxation of the bronchial muscles (but in that case cannot develop vagal symptoms), or insulin shock transiently stimulates the vagus nerve but the agent causing the relaxation of the bronchial spasm is not directly dependent on the insulin action.

On the other hand, physiologists have clearly proved, by numerous experiments on cats (Cannon *et al.*, 1924; Elaut, 1929), rabbits (Langecker, 1928), dogs (Tscherboksaroff and Malkin, 1925), mice (Elaut, 1929), and pigeons (Riddle *et al.*, 1924), that insulin shock unmistakably caused a higher production of adrenaline, found either in the blood by biological assessments (Cannon *et al.*, 1924; Tscherboksaroff and Malkin, 1925) or in the adrenal medullas by histochemical or histological investigations (Langecker, 1928; Elaut, 1929). The hyperproduction and increased dissipation of the adrenaline in those cases is a sort of regulative measure of the organism, preventing or diminishing the toxic effects of massive doses of insulin. Bearing these facts in mind, I began to apply insulin shock in cases of bronchial asthma. As the physiologists' explanation of the insulin shock action seems to be more plausible—although not yet proved in human clinics—than the original one suggested by Wegierko (1937), only those cases of bronchial asthma with an allergic aetiology were considered to be suitable for this treatment. A no less important problem

is to exclude from insulin shock treatment all types of arterial hypertension, acute and chronic failure of the circulation, and cases with even a slight impairment of carbohydrate metabolism: a more detailed account of this question will be found in the "Discussion."

Methods

Before the patients were submitted to insulin shock treatment they were subjected to the following preliminary investigations after a routine general examination:

- (1) A detailed personal as well as family history of the case was drawn up, with particular stress on the elucidation of the allergic conditions.
- (2) Examination of the circulatory system by: (a) electrocardiogram; (b) x-rays of the chest; (c) repeated control of blood pressure.
- (3) Blood examined by film and for the leucocyte count; B.S.R.; and glucose-tolerance test.
- (4) Sputum examined by culture and for eosinophilia.
- (5) Stool examined for parasites.
- (6) E.N.T. control of the nasopharyngeal region and, if necessary, local treatment.

Insulin Shock.—At 8 a.m. 20 units of soluble insulin were injected hypodermically or intravenously for the first shock. The following doses of insulin were higher by 5 or 10 units; but in cases showing a violent reaction to the first dose only an equal amount of insulin was repeated; the insulin shocks were usually repeated twice weekly; sometimes, however, in the early stages of treatment they were given three times a week. The individual insulin shock usually lasted three hours and ended in self-recovery or was arrested by the injection of 50 ml. of 20% glucose solution (only if the patient lost consciousness) or by oral administration of 300 ml. of 10% glucose solution. During the whole period of shock the following controls were carried out: (1) the blood sugar was estimated every half-hour—if necessary, also immediately before the arrest of the shock; (2) the blood pressure was measured every 10 minutes—if necessary more often; (3) somatic and mental symptoms were controlled every half-hour.

It is sometimes very difficult to decide whether the treatment is complete or not; discontinuation of the attacks or of permanent breathlessness is, of course, the best criterion in this respect. In practice, however, there is sometimes a recurrence of breathlessness, and in such cases one or two additional shocks have to be given.

Results

Eight cases of severe allergic type and 3 of non-allergic bronchial asthma lasting from a few weeks to a few years, treated previously by various generally known therapeutical methods without any obvious results, were subjected to insulin shock treatment. Particulars as to age, sex, and number of shocks given are shown in the accompanying table. The courses

of treatment varied from 6 to 9 weeks. The lowest glycaemia (18 mg. per 100 ml., Case 6) was found during a shock when 70 units were injected. It is worth mentioning that in the same case the blood sugar during the next insulin shock, when 80 units were injected, was only 24 mg. per 100 ml. In both cases the patient became unconscious several times, but only for a very short period, recovering by himself. He, however, developed a slight tremor, but predominant symptoms were those of the emotional reactions, such as crying, anger, quarrelsomeness, etc.

In all 11 cases the blood pressure rose regularly about 15 to 70 mm. Hg above the initial level, usually at the end of the

first hour of insulin shock, but this elevation never lasted longer than two hours after the blood sugar had regained the normal limits (Valis, 1945). After the treatment eosinophilia in 7 cases out of 8 dropped 10% to 60% of its initial value. I consider this symptom of great importance, since the diagnosis of an allergic cause of bronchial asthma was based almost entirely on it (Ratner, 1943), apart from the local findings of the mucosa of the nasopharyngeal region or skin changes typical of an allergic state.

Improvement in the asthmatic condition varied so much from case to case that it seems impossible to make any classification in this respect. The only feature common to almost all cases was a subjective feeling of relief of breathlessness during the shock itself, even although typical symptoms of bronchial asthma were still present; in such cases dyspnoea usually returned in a few hours. In 7 cases out of 8 complete recovery from symptoms occurred without any regularity; in each of the above-mentioned cases, when the stage of clinical recovery was reached, two additional insulin shocks were given as a matter of routine. So far the complete subsidence of asthmatic phenomena has in 7 cases lasted from 8 months to 2½ years—i.e., from their discharge from hospital up to the present time. Case No. 8 was thoroughly free of symptoms for 5 months, but recently again developed some breathlessness of asthmatic type. Although at the time of his discharge from hospital he was without any asthmatic symptoms the eosinophilia remained at its initial level; in view of this fact one might accept the fluctuation of the eosinophilia as a good criterion of the response to insulin shock, and as an indication whether or not the treatment has to be discontinued.

The 3 cases of non-allergic bronchial asthma showed no improvement whatsoever, although during the shocks each felt a transitory respite from breathlessness. In all 11 cases the blood sugar remained within normal limits after the treatment was completed.

Discussion

From the previously quoted data it becomes clear that only allergic bronchial asthma should be selected for insulin shock treatment. Since, during the shock, allergic and non-allergic cases showed a conspicuous rise in blood pressure, it seems easier to accept the physiologists' conception of the insulin shock mechanism. Thus artificially stimulated suprarenal medullas dissipate more adrenaline to the peripheral blood, causing the well-known symptom of relaxation of the smooth muscles of the bronchioles, but at the same time giving a stimulus to the peripheral circulation which produces a transitory rise in blood pressure. To offer a satisfactory explanation of a permanent or prolonged improvement in bronchial asthma by means of

Table giving an Analysis of the Cases

No	Age and Sex	Type of B.A.	Eosinophilia		Allergic Condition other than B.A.	No. of I.S.	B.P. Before I.S. Treatment	Highest B.P. During I.S.	Largest Dose of Insulin (Units)	Lowest Glycaemia (mg./100 ml.)	I.S. Symptoms	Result

of treatment varied from 6 to 9 weeks. The lowest glycaemia (18 mg. per 100 ml., Case 6) was found during a shock when 70 units were injected. It is worth mentioning that in the same case the blood sugar during the next insulin shock, when 80 units were injected, was only 24 mg. per 100 ml. In both cases the patient became unconscious several times, but only for a very short period, recovering by himself. He, however, developed a slight tremor, but predominant symptoms were those of the emotional reactions, such as crying, anger, quarrelsomeness, etc.

In all 11 cases the blood pressure rose regularly about 15 to 70 mm. Hg above the initial level, usually at the end of the

clinical experiments is a very difficult task, if not utterly impossible. Accepting, however, the mechanism of insulin shock in animal experiments, mentioned before, one has to expect a permanent hyperfunction or even hypertrophy of the adrenal medullas after the powerful stimulus of the shock has been repeated a number of times. In fact, experiments carried out on rabbits (Langecker, 1928) and pigeons (Riddle *et al.*, 1924) have shown that repeated injections of small doses of insulin are able to develop hyperfunction and hypertrophy of the whole suprarenal gland. Elaut (1929) produced in rabbits, cats, mice, and dogs by a single shock an undoubted hyperfunction of the adrenal medullas, demonstrated by histological and histo-

chemical evidence. If, then, insulin shocks produce hyperactivity or hypertrophy of the adrenal medullas why should this hyperactivity operate in human beings only in the prevention or treatment of bronchial asthma and not lead to the syndrome of suprarenal hyperactivity? The answer to that question lies in Cannon's (1924) experiments in which he showed that the suprarenal medulla works as an emergency measure, by "explosive" liberation of the adrenaline only when stimulated either by nervous impulses or by toxic agents, such as insulin.

From this explanation it also becomes clear that all types of arterial hypertension should be excluded from this kind of treatment. Since, during insulin shock, blood pressure rises transiently to a considerable degree, all types of acute or chronic circulatory failure should also for obvious reasons be eliminated from this therapeutic measure. It has been repeatedly shown (Langecker, 1928; Riddle *et al.*, 1924; Gourmaghtigh, 1931) that insulin in big doses stimulates not only the medulla but also the cortex of the adrenals, which, as is known (Pflüger, 1942), performs through its steroids a powerful antglycolytic action, and thus cases with impaired carbohydrate tolerance must also be excluded from insulin shock treatment.

Chemically, insulin is a protein, and as such, injected into the organism, it might precipitate two different independent actions: (a) as protein introduced parenterally it might sometimes cause more or less pronounced symptoms of anaphylactoid shock; (b) as a glycolytic hormone it causes hypoglycaemia. The former action might begin almost immediately if the insulin is injected intravenously, or later if it is injected subcutaneously. One of the numerous symptoms of anaphylactoid shock is the fall in blood pressure, bradycardia, etc., and this may be the reason why Wegierko (1937) found these symptoms in some of his cases—which led him to the conclusion that vagal stimulation brings relief in breathlessness during insulin shock. In one of my latest cases of bronchial asthma, not included in the present series, three minutes after the first intravenous injection of 20 units of insulin the patient developed symptoms of anaphylactoid shock with severe dyspnoea of asthmatic type, and the whole incident was closed by the injection of adrenaline. The second action of insulin begins in about 30 minutes from its injection and reaches its peak in about 60 minutes; this is also the point when anti-insulin agents of the organism start to operate. The symptoms of the first protein phase are met by adrenaline, dissipated from the medulla as a response to the hypoglycaemic action of the insulin; at this point symptoms of the first phase (fall in blood pressure, bradycardia, etc.) might be mixed with symptoms of the second phase (hypoglycaemia) and symptoms of the third anti-insulin phase (rise in blood pressure, tremor, etc.) caused by dissipation of adrenaline and consecutive relaxation of bronchospasm. The next phase is the complete disappearance of all symptoms of the first protein phase with persistent symptoms of adrenergic type.

Summary

Out of a total of 8 allergic bronchial asthma cases 7 responded to insulin shock treatment, with complete disappearance of symptoms to the present time—i.e., from 8 months to 2½ years. One allergic case responded with a transitory subsidence lasting 5 months.

Three cases of non-allergic type bronchial asthma did not respond to this treatment although during the shock itself each of these patients felt relief for a few hours.

Insulin shock treatment in bronchial asthma seems to operate by means of a stimulus to the adrenal medullas, inducing a hyperproduction and dissipation of adrenaline; this action must be regarded as a defensive measure of the organism itself against the toxic action of massive doses of insulin.

CARCINOMA OF THE LIP AND ITS TREATMENT BY RADIUM (1928-44)

BY

ALEXANDER A. CHARTERIS, M.B., Ch.B., D.P.H.,
F.R.F.P.S.

(From the National Radium Centre, Western Infirmary, Glasgow)

The purpose of this communication is to comment briefly on the cases of cancer of the lip referred to the Radium Department of the Western Infirmary, Glasgow, during the years 1928-44 inclusive, and to give details of the methods employed as well as of the results obtained. During this period of seventeen years 293 cases were sent to the department, but 47 were not treated. It must be explained that only 9 of these were rejected as cancer cases too advanced for any sort of treatment; many extensive lesions have been tackled, irradiation being withheld only when it was clear that no benefit would result from treatment. The patient's general condition contra-indicated any kind of intervention in 3 other instances, while 5 more refused any form of treatment; for the balance of the 47 rejected cases surgery was deemed more suitable and convenient owing to the small size of the lesion. The 246 patients who received treatment are therefore not a selected group, but include all stages of the disease, with and without invasion of lymphatic glands, up to those with extension beyond the actual lip area. The result as regards cervical glands is still doubtful in 4 cases treated late in 1944, and so the final group for analysis totals 242. Experience shows that the success or failure of treatment is usually obvious in one year, and so the analysis is taken up to the year 1944: this unusual fact will be dealt with more fully when speaking of results.

General Observations

The primary lesion favoured the lower lip as usual, only 8 being on the upper, while a second primary lesion appearing on the opposite lip at a later date was observed in one upper-lip case and two lower-lip cases, further treatment being successful. With eight exceptions the patients were males, and no special aetiological factors were observed, except possibly the influence of exposure at work. During the earlier years the blood Wassermann reaction was not ascertained as a routine, but it is striking how seldom in buccal carcinoma one meets with a positive result even when leucoplakia is present. Microscopical confirmation was sought only in 75 cases where some doubt existed: there were 3 cases in which the diagnosis of malignancy was doubtful. In most of the patients the diagnosis was quite obvious. By far the greatest number of cases occurred in the fifth, sixth, and seventh decades, but age appeared to have no influence either in the results or on the frequency of glandular metastases. Six patients were under 40 and thirteen over 80 years of age, the latter group doing very well indeed.

Features of Lip Carcinoma

The rational radiotherapy of malignant tumours must depend on the recognition, amongst other things, of the intrinsic biological peculiarities of the varying types of lesion encountered at different sites in the body, or even in the same organ. For example, lingual carcinoma may present a wide range of differentiation from more adult types, but there is usually a great tendency towards glandular metastases. Cancer of the lip, however, is mostly of fairly adult and radio-resistant character, calling for a rather high level of dosage and spreading much less often to the related lymphatic glands. The rate of growth is not often rapid, and this fact, together with the exposed site, helps to make the patient seek advice at a reasonably early stage in the disease. Nevertheless, cases are still seen in which extension has occurred either over the chin or to alveolus, cheek, and upper lip. Such lesions can often be dealt with satisfactorily so long as the mandible itself is not invaded. Of this series 51 had lesions of this degree. The teeth should receive attention before treatment, but only in bad cases of dental sepsis is clearance of the mouth essential.

Adequate treatment of the cervical lymphatic glands is much more difficult than that of most buccal primary growths, and the attitude taken towards these lip cases is dictated by the

pathological considerations just mentioned. Of the cases 208 had no obvious involvement of glands at the time of the primary treatment, and, although the neck was not dealt with, only 19, or about 9%, developed cervical metastases at a later date. The policy with lip cases has therefore been to treat the primary lesion only, and rely upon the routine follow-up examinations to detect any development in the neck at an early stage.

Methods of Treatment

Implantation of radium has been in use from the earliest days, but adjustment of tissue dose, as regards both needle pattern and time factor, had little scientific basis at that time. The growth of physical knowledge has changed this, and efficient treatment is now possible without tissue damage and comparatively little in the way of post-radiational stigmata. The needles employed have a linear intensity of 0.6 mg. of radium element per cm. of active length, and those with a total length of 44 mm. (2 mg. Ra el.) and 32.7 mm. (1.2 mg. Ra el.) have proved most useful. The conservative nature of radiotherapy enables one to treat a wide area, and two common arrangements are a 4.5×2 cm. rectangle (three 2-mg. Ra el. closed at each end by a 1.2-mg. needle) or a 5.5×2 cm. rectangle (six 1.2-mg. needles in tandem pairs, closed at each end by a needle of the same strength). It will be noted that the strength of each line is uniform and so the dose rate must show a rise towards the centre of the area, but the results from every point of view have proved so good that no adjustment has been made. The dose delivered 0.5 cm. from the needle plane in 168 hours varies between about 5,000 r and 6,000 r, with a maximum of 6,700 r towards the centre. The extreme corners of these rectangles fall to a total dose of about 4,000 r, but with the margin provided this part is not in the tumour zone.

Preparation of the skin is important if sepsis is to be avoided. Preliminary removal of any crusts is carried out, and in the theatre soap and water, spirit, and then proflavine oleate 1% in liquid paraffin are used. Simple infiltration by 2% novocain containing adrenaline gives efficient local analgesia after pre-medication by omnopon (1/3 gr. (22 mg.) hypodermically). After careful measurement the implantation is carried out, each needle being stitched in place with silkworm-gut: the whole bundle of silk threads is stitched to the skin. The part is painted with proflavine oleate again, and powdered with sulphanilamide. A light gauze dressing held by a four-tail bandage is the most suitable and comfortable covering. For a week the diet will be fluid or semi-solid, and simple mouth-washes with an occasional dose of aspirin should keep the patient fairly comfortable. Luminal—1 gr. (65 mg.) by mouth at night—is sometimes helpful. Removal of the needles presents no difficulty, and sepsis is a rare complication. No external dressing is required thereafter, the part being dusted with sulphanilamide powder to seal the punctures.

The use of *double radium moulds* for treatment of the lip is the second method which has been employed. This causes no trauma, and from a physical point of view is desirable as giving something nearer a homogeneous distribution than an implantation. A few moulds curved round the lip were attempted before the days of proper physical control, but this method was put on a scientific basis only as a result of the work of Paterson and Parker (1934), the name of J. S. Fulton being specially associated with the technique. From a plaster cast a dental apparatus is worked up in a form suitable for holding a plane of radium needles inside the lip, an outer piece held to this by screws being used to irradiate the skin surface simultaneously. The apparatus is worn for some 8 hours per day with at least one rest, and treatment lasts for about 10 days. With a radium-mucosa distance of 0.5 cm. and radium-skin distance of 1 cm., about 6,000 r is given throughout the lip: the mucosal dose is inevitably higher than this, but no untoward effects will ensue.

After-treatment of the lip is directed to control of the necessary reaction. The skin will show a deep erythema occasionally amounting to moist desquamation unless it is kept dry. The area is not washed, but is dusted with powder from time to time; both sulphanilamide and boric powder have their uses. The patient's co-operation in keeping the skin dry is of the utmost importance. The mucous membrane shows its charac-

teristic "film" of fibrinous exudate, calling for simple mouth-washes, aspirin, and a suitable bland diet. If the lip edges tend to stick some vaseline can be used there, but it is not allowed on the skin. Exposure is to be avoided during the earlier stages of the reaction. The process will have subsided completely in from four to five weeks, and only the first two should have been troublesome for the patient.

The *treatment of cervical glands* does not lend itself to such easy description, the diversity of methods in general use being sufficient indication of the difficulties encountered. The records of our cases mention implantation, resection, radium moulds, x-ray therapy, and radium beam therapy, and it is impossible to attempt any further comment at the moment, except that surgery and implantation of radium are the methods showing most promise. Work is proceeding on the general problem of treatment for malignant glands in the neck, but it will be some time before any definite pronouncement can be made.

The *after-effects of irradiation* of the lip have been studied with regard to the occurrence of tissue damage or excessive skin change, both of which would be particularly undesirable at such a site. As all surviving patients are followed up indefinitely this task has been comparatively easy. After any radical irradiation for malignant disease some degree of fibrosis and endarteritis must be present in the tissues, but in a properly treated lip case there should be no conspicuous change unless destruction by tumour has been such as to cause gross loss of substance and therefore deformity.

Naturally all patients show epilation over the treated area. This is not normally very obvious, but in the case of a man with a dark beard there may seem to be a zone of pallor even where skin change is minimal. With regard to the grosser signs of previous irradiation, 67 of the cases are recorded as showing some definite evidence of scarring, with or without telangiectases. Two cases present leucoplakia with hyperkeratosis, which merely demonstrates once more the fact that this condition responds only temporarily to irradiation: pre-existing leucoplakia will therefore reappear after treatment, although an associated tumour may be satisfactorily healed. Actual tissue damage in the form of late necrotic ulcers has been seen in 6 cases, but 4 of these were treated during the period 1929-31, when no physical control was possible. As might be expected, 5 of these 6 had been treated by implantation, but it is now felt that careful measurement of the needle pattern and placing of the plane in the centre of the thickness of the lip can almost completely obviate undesirable effects. All these necrotic lesions healed with some scarring. None was of greater extent than 1 cm. in diameter, and the lip was never perforated.

Results of Treatment

In the accompanying table an attempt has been made to show how the different groups have reacted to treatment. A small group (B) has been segregated, since irradiation was preceded by excision of the primary lesion. This method was occasionally employed during the earlier years before radiotherapy was so generally adopted for neoplasms of the lip, most of the cases being those in which there was some doubt as to the completeness of the operation. The other sections indicate clearly the good results obtained from treatment of the primary lesion, and show how these deteriorate at once when the cervical glands become involved. Three of the cases in Group C were implanted after excision; but, in view of the obviously satisfactory results achieved in the lip itself, it was thought undesirable to add to the number of groups by presenting them separately. It will be seen that when the cases are not complicated by glandular invasion (Group A), 165 (94%) patients out of a total of 175 were rendered free from disease; or, if the 9 cases requiring accessory excision be excluded, 156 out of 175 (89%). In the table these results are indicated separately for the implant and mould methods.

Where glands were present to begin with, or developed at a later date, the picture is very different, and, although the lip was healed, only 25 out of 53 cases (Groups C and D) were rendered free from disease, this representing about 48%. If all cases treated, with or without glands, are considered, it is found that a satisfactory result was achieved in 83%, but if the rejected (untreated) cases, totalling 47 less 16 operated upon satisfactorily, be added, this figure falls to 73%. The

term "failure" in the table means that the patient died of cancer, usually about a year from treatment. The failures include two fatalities in the form of one anaesthetic death during excision of a primary lesion which had failed to respond and one case of phlebitis with generalized sepsis following operation on glands.

Cancer of Lip, 1928-44 242 Cases treated

	Implant for Lip (168 Cases)	Moulds for Lip (74 Cases)
A Cases without glands or glandular development	Healed 85 Healed died later of other cause 26 Residue or small recurrence excised well 6 Failure 3	32 13 3 7
	Total 120	55
	Free from disease 117 (97%)	43 (87%)
	Free from disease (radium only) 111 (92%)	43 (81%)
B Cases without glands or glandular development, excising then radium for lip	Healed 8 Healed died later of other cause 2 Failure 0	3 0 1
	Total 10	4
C Cases with glands when first seen	Healed 10 Healed died later of other cause 3 Failure (due to glands) 12	1 1 7
	Total 25	9
D Cases which developed glands after successful treatment of lip	Healed 5 Healed died later of other cause 1 Failure (due to glands) 7	2 2 2
	Total 13	6
Totals	168	74

It appears to be a feature of lip carcinoma that in the great majority of cases the result is known in about a year, and the frequency with which this was found made it reasonable to include patients up to the year 1944. The result for every case has been scrutinized to determine this point, and it is a remarkable fact that every failure in the whole 1928-44 series has been obvious in the first year with but 7 exceptions. In only one of these was there a truly late recurrence of disease: the patient was treated successfully in 1931 for the lip, which remained healed, but in 1935 he developed a glandular metastasis, and this proved fatal, no other primary lesion being found. Although the other 6 patients lived two to three years after treatment, within a year it was quite obvious in 4 of these that the patient would die of cancer of the lip or glands, while in another the cause of death was development of an independent antral carcinoma. Only in the one remaining case was the issue in any doubt till 18 months from the time of treatment. It is for those reasons that the survey has been taken up to so recent a date, and this fact must be emphasized, since such a procedure could not ordinarily be adopted while recording cases of cancer.

Owing to the age of many of the patients, a number died of some other complaint a period of years afterwards of all those shown in this category only 24 died within the first five years, the remainder of deaths being at intervals up to thirteen years.

Conclusions

The facts adduced show that the use of radium is a satisfactory radiotherapeutic method for cancer of the lip, although adequate treatment of the cervical glands still presents a serious problem. It is suggested that surgery and implantation of radium are the most promising methods for the neck, but certain work on the radiotherapeutic approach to this problem is not advanced enough for more to be said at present.

The cases treated by implantation of the lip include the worse ones, since the mould method is not readily adaptable to very bulky lesions or those spreading beyond the lip, yet the tabular statement shows that implant results are superior to those obtained by the use of moulds. Moreover, implantations throw less work upon a radiotherapeutic department, and also

on the ward nursing staff, so that this is now regarded from all points of view as being the method of choice for radium.

The malign influence exerted upon results by invasion of cervical glands is strikingly illustrated, but it is shown that the percentage of cases developing this complication is a small one.

It is with pleasure that I acknowledge indebtedness to my colleagues on the visiting staff of the Western Infirmary for their friendly co-operation in giving me every facility, both in wards and in operating theatres for the necessary radiotherapy, to our physicist, Dr McFarlane for working out the dose rates in the standard implants and also any special ones, and particularly to my clinical assistant, Dr W Allan Crawford, for much painstaking work in extracting from our records the details upon which this paper has been based.

PYLORIC STENOSIS: SELECTIVE MEDICAL AND SURGICAL TREATMENT

FIFTY SUCCESSIVE CASES WITHOUT A DEATH OR FAILED MEDICAL TREATMENT

By

N. M. JACOBY, M.D., M.R.C.P.

Consultant Paediatrician Kent County Council, Registrar to the Children's Department, Guy's Hospital

The surgical treatment of congenital hypertrophic pyloric stenosis is now a very safe procedure in skilled hands, and Levi (1941) and Paterson *et al* (1941) have published large series of cases with a mortality rate below 5%. Although many who have given medical treatment with atropine methylurate a trial know that it will cure some cases, they have in the main abandoned the method. This is because they fear the high mortality rate in the "failed medical case" which subsequently has to have an operation. Some administer "eumvdrin" for a few days and if vomiting does not rapidly cease submit the infant to operation. Such a procedure nearly always fails and in fact it would have been better if the child had been operated on at the beginning. The result of all this has been a swing of opinion back to the view that Ramstedt's operation is the method of treatment for all cases. It is certainly obvious that any alternative method must be able to offer an equal degree of safety.

Jacoby (1944) suggested certain criteria for selecting individual cases for medical or surgical treatment, and had at the time treated 26 cases, with a mortality rate of 8%. Since then considerably more experience of the method has been obtained, and it can now be reported that 50 successive cases have been treated without any fatalities, and what is equally significant, not one of the 26 cases selected for medical treatment failed to respond readily or had to be subjected to operation. On these results it seems reasonable to suggest that medical treatment has a definite part to play, for not only does it avoid unnecessary operations but in certain cases—e.g. where there is secondary infection or diarrhoea—it is probably safer than operation. Moreover in certain suitable cases, admission to hospital can be avoided altogether.

Method of Medical Treatment

It must be stressed that the medical treatment advised in the original paper, and employed ever since is different from that in general use. The main difference lies in the radical reduction of feed volume at the beginning of treatment; and this is vitally important, as without it early cessation of vomiting cannot be expected. I believe that, irrespective of what quantity of feed passes the pyloric sphincter before vomiting occurs the actual vomiting itself is highly undesirable, because it both weakens the infant and fills the attendants with gloom. It appears that atropine methylurate takes three or more days to exert its full effect, and it is probable that during these waiting days the cessation of vomiting is due mainly to feed-volume reduction. At the same time it is obvious that this method of treatment is totally unsuited to a severely dehydrated infant, and in such circumstances should never be used.

To achieve a satisfactory result with medical treatment the following procedure is advised:

1. Exact diagnosis by unmistakable palpation of a "palpable pyloric tumour."
2. Careful selection of cases according to the criteria given.
3. Reduction of feed to 1 oz. (28 ml.) four-hourly in infants under 6½ lb. (3 kg.), and 1½ oz. (42 ml.) in infants over 6½ lb. Breast milk is preferable, but whatever feed is used it should be of full strength.
4. Atropine methylnitrate 0.6% in alcohol—4 drops from a "fountain-pen filler" into the back of the mouth, 15 minutes before four feeds on the first day and then before three feeds on the second or third day; when vomiting has completely stopped, 2 drops three daily for about 16 weeks.
5. No stomach-washing unless the vomit contains large amounts of mucus.
6. No parenteral fluids by any route. A case that is in real need of hydration should be operated upon as soon as possible.

Method of Surgical Treatment

The method of surgical treatment used in this series was that advised by Levi, except that the feeding-chart was modified so as to take nearly six days after operation before full-strength milk was reached.

Criteria for Selection of Cases

The criteria for selection of cases have not been altered since the original paper, though an extra contraindication to medical treatment (haematemesis) has been added. It may perhaps be convenient to recapitulate them here.

1. Indications for Surgical Treatment :
 - (a) Vomiting beginning in the second week or earlier.
 - (b) Severe dehydration.
2. Contraindications to Surgical Treatment :
 - (a) Infection.
 - (b) Diarrhoea.
3. Indications for Medical Treatment :
 - (a) Vomiting starting in the fourth week or later.
 - (b) Vomiting continuous for three weeks or more before the infant is first seen, provided it is not severely dehydrated.
4. Contraindications to Medical Treatment :
 - (a) Severe dehydration.
 - (b) Haematemesis.

Table giving an Analysis of Results

	Medical Cases	Surgical Cases
Total cases	26	24
Male	22	21
Female	4	3
Average age at onset of vomiting	4 weeks	2.7 weeks
Average age on admission	6.3 weeks	4.7 weeks
Average birth weight	7.3 lb. (3.3 kg.)	7.3 lb. (3.3 kg.)
Average weight on admission	8.1 lb. (3.67 kg.)	6.7 lb. (3.04 kg.)
Number breast-fed	12	13
Number artificially fed	14	11
Average no. of days in hospital	13.4	13

These results show very much what would be expected if the criteria were followed. One point, however, is particularly worthy of note, and that is that 50% of the patients were artificially fed. Inquiry as to the reason for discontinuing breast-feeding revealed that in almost every case it was in the belief that the vomiting was due to the breast milk disagreeing with the infant. It cannot be too strongly emphasized that such a condition does not exist, and that artificial feeding can only lead to a worsening of the condition.

Selected Case Reports and Comments

When selecting cases for medical or surgical treatment it is found that in the majority a decision is soon arrived at. There are, however, certain cases in which the various indications and contraindications balance each other, with the result that personal judgment has to be used. The following selection of cases attempts to show how some of these problems were dealt with.

Case 1.—Female, aged 6 weeks; artificially fed; birth weight, 7½ lb. (3.4 kg.). Vomiting started at 5 weeks. On admission the child was collapsed and seemed moribund. The weight had fallen to 6 lb. 5 oz. (2.87 kg.); the temperature was 102° F. (38.9° C.). She

was very dehydrated and was having quite severe haematemesis. It was obvious that no form of treatment other than resuscitation could be undertaken. At the end of 36 hours she was fully hydrated by parenteral means, the temperature had fallen to 98° F. (36.7° C.) and the condition was much improved. As she now appeared, the indications were for medical treatment, but in view of her previous dehydration and haematemesis it was decided that operation must be performed. Recovery was uneventful.

Case 2.—Aged 11 days; birth weight, 8 lb. (3.6 kg.); breast-fed. Vomiting started on the seventh day. Weight on admission, 7 lb. 12 oz. (3.5 kg.). The infant was having six loose green stools daily and had an upper respiratory infection and sepsis at the umbilicus.

Normally, cases that start vomiting so early should be operated on, but here it was felt that the diarrhoea and respiratory infection made this a dangerous procedure. Medical treatment was started, and vomiting had completely ceased by the third day. The patient was fit for discharge by the tenth day.

Case 3.—Aged 2 months; birth weight, 5 lb. 10 oz. (2.55 kg.); artificially fed. Vomiting started at 2 weeks. Weight on admission 5 lb. 9 oz. (2.52 kg.). Was severely dehydrated and having tetanic spasms. Because of the very long period of vomiting associated with dehydration it was felt that rapid relief was required, and an operation was performed forthwith. Seven days later the stools became loose and frequent. The child was given a blood transfusion and then dextrose-saline for 24 hours, and was put on to peptonized breast milk. The stools rapidly improved, and the feed was gradually changed to peptonized artificial feed, which was slowly depeptonized. This infant through its long period of semi-starvation had almost lost its tolerance for food, and after operation presented a feeding problem.

Summary

Fifty cases of congenital hypertrophic pyloric stenosis were dealt with by selective medical and surgical treatment. There were no deaths and no failures of medical treatment.

A method of medical treatment involving feed-volume reduction is described.

Criteria for the selection of cases for medical or surgical treatment are given.

Medical Memoranda

Diphtheritic Encephalomyelitis

Nervous symptoms, complications, and sequelae of diphtheria occur often enough. They are clinically important though peculiar in type. Their pathology and pathogenesis are not yet perhaps completely understood. References in the literature to diphtheritic encephalomyelitis are very few. Querido (1928), who recorded a case of post-diphtheritic encephalitis, remarked that parenchymatous inflammation of the central nervous system is the rarest sequel of diphtheria. Hall (1932) reported a fatal case of acute toxic encephalitis in a female child aged 18 months. In addition to membrane in the pharynx, from which diphtheria bacilli were cultivated, the necropsy showed distension of cerebral vessels, with linear haemorrhages throughout the white matter.

Below is recorded a fatal case of encephalomyelitis which occurred as a complication of faucial diphtheria. The extreme rarity of the condition warrants this report.

CASE HISTORY

A Sikh male child aged 15 months was admitted into the children's ward with the complaint of unconsciousness with convulsions, duration three days. The onset was sudden. About a fortnight back the child had had vomiting for four days and fever for two days. There was no other history of significance. On examination the patient was comatose; temperature 97.4° F. (36.3° C.), pulse 110, and respirations 26 per minute. The pupils were moderately dilated and reacted to light. The neck was soft, and Kernig's and Brudzinski's signs were negative. There was left hemiplegia. Tendon-jerks were exaggerated and Babinski's sign was extensor on both sides. The tonsils were enlarged, with a small suspicious membrane on the left. Other systems were normal.

Investigations.—**Fundi:** Only slight bilateral venous congestion was present. Cerebrospinal fluid: 15 ml. of clear sterile fluid was drawn out under high tension by lumbar puncture; a few mono-

ates were found; protein was present in traces, sugar 55 and chloride 650 mg. per 100 ml. Blood: Total white cells, 20,500 polymorphonuclears 92%, lymphocytes 5%, and large mononuclears 3%; no parasites. A throat swab revealed a fair number of diphtheria bacilli (confirmed by culture), streptococci, and *M. catarrhalis*. Urine: Acetone present in fair amount. Stool, normal. Wassermann reaction of the cerebrospinal fluid, negative.

Progress and Treatment.—Antidiphtheria serum (32,000 units) as injected intramuscularly. He was put on three tablets of cibazolid 4 minims (0.24 ml.) of nikethamide t.d.s. by mouth per day. Next day a throat swab was again examined and a fair number of diphtheria bacilli, streptococci, and *M. catarrhalis* were seen. 40,000 units of serum were injected intramuscularly. After 24 hours 20 ml of clear cerebrospinal fluid was drawn out under high tension. The fluid, which was sterile, showed protein in traces, sugar 46 mg. and chloride 650 mg. per 100 ml.; a few monocytes were present. A throat swab showed a few diphtheria bacilli. Another intramuscular injection of 40,000 units of serum was given. Next day a throat swab showed no diphtheria bacilli even on culture. 30 ml. of clear cerebrospinal fluid was drawn out under very high tension. The patient's condition gradually worsened and the coma deepened. He started having fever ranging up to 102° F. (38.9° C.), and the pulse rate varied from 120 to 140 per minute. The pupils were dilated and red. Another 10,000 units of serum were injected. The patient died after a further two days. On the last day the child was deeply comatose; temperature 102.4° F. (39.1° C.), pulse rate 170 per minute; pupils widely dilated and fixed. During the last two days seeds and medicines had to be given by the nasal route. Necropsy was not possible.

My thanks are due to Major-Gen. H. C. Buckley, M.D., F.R.C.S., C.S.I., M.S., Principal, Medical College, Agra, for his kind permission to publish his report and also to my colleagues of the pathology and biochemistry departments for the valuable help I received in investigating the case. I wish to express my appreciation of the services of my house-physician, Dr. B. P. Kacker, and the nursing staff in the treatment of the case.

A Case of Dysphagia in a Woman aged 78 cured by Tonsillectomy

The following case is of interest because, although dysphagia due to chronic hypertrophy of the tonsils is well known in children, it must be extremely rare in the aged, whose tonsils are usually atrophic.

CASE HISTORY

Mrs. W., aged 78½, was first seen on June 28, 1945, when she complained of pain on swallowing. She could not get any solid food down, and nearly choked when drinking water. She had lost 4 st. (25.4 kg.) in weight and was too weak to do her own housework. She also complained of a vague aching sensation in the left side of her throat.

On examination she had a painful enlargement of the left upper cervical glands, and at the time it was thought that the enlargement was probably inflammatory. It was found that the tonsils were chronically hypertrophied and almost touching in the midline. The nose was normal, and on indirect laryngoscopy there was no excess secretion in the laryngopharynx, which is usual in cases of post-ricoid carcinoma. It was thought that the dysphagia was probably due to the enlarged tonsils, but that tonsillectomy was definitely out of the question. She was asked to report back in two weeks' time for a review.

The patient did not return again until Oct. 11, when her complaints were just as bad as ever; the condition of the throat had not changed. After great deliberation she was advised to come into hospital either for diathermy of the tonsils or for removal of one tonsil to begin with. She was admitted on Oct. 23, and with pre-operative seconal gr. 3 (0.2 g.) and omopon gr. 1/3 (22 mg.), the anterior and posterior faucial pillars were injected with a local anesthetic. Dissection of the first tonsil was started, but this caused great respiratory embarrassment, and it was decided to remove both tonsils with a guillotine. The tonsils were mobile and easily enucleated with minimum discomfort. There was little bleeding, and both tonsils were removed within one minute. There was no post-operative complication, and the patient was returned to bed and almost immediately found swallowing greatly improved. She was discharged in one week.

Nothing was heard of the patient until February, 1946, when she was admitted on to the ophthalmic side for a dacryocystectomy. At this time she stated that she was better immediately after tonsillectomy, was eating and drinking normally, had put on weight, and had again started doing her own housework and washing. She was sleeping well at night. Examination of her throat showed that the tonsillar fossae were clear and the faucial pillars intact; there was minimal scarring.

I would like to thank Mr. W. M. Munby for permission to publish this case.

General Infirmary at Leeds.

Reviews

THE GROWTH OF CHILDREN

Nutrition and Chemical Growth in Childhood. By Icie G. Macy, Ph.D., Sc.D. Volume II. Original Data. With foreword by Lawrence Reynolds, M.D., and a Supplement by Julia Outhouse Holmes, Ph.D. (Pp. 1,450; illustrated. \$10.00.) Springfield: Charles C. Thomas.

The results of ten years of research have been embodied in *Nutrition and Chemical Growth in Childhood*, and in Vol. II, issued under the subtitle "Original Data," the facts and figures are fully presented. Dr. Icie G. Macy, who is director of the research laboratory of the Children's Fund of Michigan (the sponsors of the investigation), presented in Vol. I the methods used and the average results obtained. Here she gives in great detail the results of over 600 five-day metabolic balance periods conducted on twenty-one boys and girls. In addition the present volume contains the results of studies of the nitrogen, calcium, and phosphorus metabolism of a further twelve pre-school boys and girls conducted under the direction of Prof. Julia Holmes. The first impression is confusing. The volume is not suitable to be looked through as a continuous text, but careful reading of the study of, say, one or two children begins to bring out the value of the data. Of this there can be no doubt, and more detailed study induces a sense of high regard for the patience and ingenuity shown by the team of workers and the splendid co-operation of the children. Indeed, if there is such a thing as professional training for suitable employment as subjects for physiological and especially nutritional research, these children have had it, and should be certain of steady employment for the rest of their lives!

Vol. III is planned to give the interpretation of the results obtained, and when it is available it will be easier to assess the ultimate value of the tremendous undertaking. It is fair to say of this present volume in isolation that the complicated trees of analytical data obscure the wood of true knowledge. Nevertheless, all workers in the field of nutrition and metabolism will find in it some valuable help, whether it be in relation to problems of growth, with which the whole research project is fundamentally associated, or to special details of the individual chemicals studied. As is pointed out in a foreword, nearly one-third of American recruits in the recent campaign were rejected for physical defects. "A sad commentary," says the writer, Dr. Lawrence Reynolds, "on our boasted wealth and industry." The Children's Fund of Michigan was established "to promote the health, welfare, happiness, and development of the children of the State of Michigan, primarily, and elsewhere in the world." This work of Dr. Macy is an important contribution to that end.

GUIDE TO POST-WAR EUROPE

Health Recovery in Europe. By Sir Arthur S. MacNalty, M.D., F.R.C.P., F.R.C.S., and W. Franklin Mellor. (Pp. 180. 7s. 6d.) London: Frederick Muller Ltd.

This little book is an essay in shadow and subdued light. In the first part of it an account is given of health and nutritional conditions in Europe during and since the war. The authors have continually to apologize for fragmentary and imperfect statements and the lack of precise information, though enough is given to depict a situation which in some parts of the Continent seems to be desperate beyond remedy. That wholly unrelated diseases should have reached their peaks of incidence at about the same time all over the Continent is the last and in some ways the sorriest of the many strokes of Fate. This book made its appearance during the first General Assembly of the United Nations. Even while the delegates were sitting in London the picture was darkened by news of the failure of crops in various countries and the shadow of famine crept closer. Here was an opportunity, with the leaders of nearly all the nations meeting together, for them to sit down and plan to avert the worst calamity. But they did nothing of the kind. They talked politics, not economics; they wrangled over issues relatively unimportant instead of arranging for the pooling of resources and the opening of highways of distribution; and they passed an empty resolution on the food question and went their way with the words of the British Prime Minister in their ears that the success achieved had been remarkable! The proceed-

ings of the United Nations lend an ironic touch to the optimistic title of this book and to the pious ascription at the end, that if the United Nations wield the sword for the coming battle against disease as well as they did the sword of war, then victory is assured.

The story of medical relief work is well told. Four principal bodies have been concerned in health reconstruction: the Civil Administration of the military authorities, U.N.R.R.A. with its Health Division, the voluntary agencies such as the Red Cross and Order of St. John, the Friends' Relief Service, and the Save the Children Fund; and finally the national health and medical services of various countries. One of the two most hopeful elements in the situation is the development of the public medical services, the other being the availability of new remedies and means of combating disease. On one point epidemiologists are still in the dark. The authors say that influenza, which made such terrible ravages in 1918-19, is the only important epidemic disease which has been comparatively unaffected by war conditions. Such outbreaks as have occurred have not even equalled in severity three or four which took place in the inter-war years.

The authors, one of whom is a former Chief Medical Officer of the Ministry of Health and the other a former member of the Health Section of the League of Nations Secretariat, have produced a book which, despite its inevitable gaps and guesses, will be of real use to international health workers. Some day, no doubt, a complete authenticated and statistical record will be compiled.

MEDICAL TREATMENT

Textbook of Medical Treatment. By Various Authors. Edited by D. M. Dunlop, M.D., L. S. P. Davidson, M.D., and J. W. McNee, M.D. Fourth edition. (Pp. 923. 30s. plus 8d. postage.) Edinburgh: E. and S. Livingstone.

This *Textbook of Medical Treatment* by a group of Scottish authors has established itself as the standard work on the subject. It is informed by a spirit of urbane rationalism which avoids alike the perils of therapeutic nihilism and of credulity, and it is written in a gracious and harmonious style instead of being a mere catalogue of remedies. It is not surprising, then, that it has reached a fourth edition, and this edition is to be particularly welcomed because of a change of format. The book is now taller and slimmer, and though austerity has narrowed the margins the type is clear and legible. The price is very reasonable for a book of this size.

The last eighteen months have been a difficult time in which to revise a textbook owing to the continuous reassessment of the sulphonamides, penicillin, and thiouracil. The doses of penicillin here suggested are on the whole smaller and the enthusiasm for thiouracil greater than many of us would exhibit to-day. Penicillin has replaced pentnucleotide in the treatment of agranulocytosis and neo-arsphenamine in Vincent's angina. Less forgivable is the scant notice paid to homologous serum jaundice, which has been the major therapeutic catastrophe of the war. It would not do, however, to end on a note of criticism, and we should like to congratulate the editors on having made available so admirable an account of modern medical treatment, particularly at a time when so many graduates are refurbishing their knowledge for the tasks of peace.

RUDIMENTS OF PSYCHIATRY

A Handbook of Psychiatry. By Louis J. Karnosh, M.D., Sc.D. With the collaboration of Edward M. Zuckerman, M.D. (Pp. 302; illustrated. 25s.) London: Henry Kimpton. 1945.

The authors have set out to prepare a comprehensive but short survey of modern psychiatry in terms which are as non-technical as possible and with the avoidance of unnecessary theory and speculation. They aim at giving the general practitioner who does not seek to become a psychiatric specialist a readable account of everything included under the heading of psychiatry, and at the same time a ready reference book in which he can quickly find what he wants to know about the diagnosis and treatment of any patient with whom he is confronted. In this ambitious task they have succeeded reasonably well, giving prominence to the type of case which is most commonly encountered, though the psychoneuroses, which must surely outnumber enormously even the cycloids and schizoids in any doctor's practice, occupy a late position in the book. Due notice is taken of psychosomatic medicine, psychopathic personalities,

and the war neuroses, and there is the usual chapter psychiatry and the law which again exposes the somewhat unsatisfactory state of this relationship. Treatment is described in sufficient detail, though it is obvious that the judgment which can decide on the right treatment for the particular case can come only from long experience of disorders of personality. Rule-of-thumb methods are even less appropriate in dealing with mental disease than they are when applied to physical disease. Case histories, and photographs of patients as well as of tissues, illustrate and enlighten the text of a book which is to be recommended. It is certainly as good as any volume of this limited scope can be.

A TEXTBOOK OF PHYSIOLOGY

Howell's Textbook of Physiology. Edited by John F. Fulton, M.D., with the collaboration of Donald H. Barron, John R. Brobeck, Robert W. Clark, George R. Cowgill, William U. Gardner, David I. Hitchcock, Harold Lampert, David P. C. Lloyd, Leslie F. Nims, and Theodore C. Rock. Fifteenth edition. (Pp. 1,304; illustrated. 40s.) London: W. B. Saunders Company. 1946.

This important textbook has been very thoroughly revised by the new editors under the leadership of Prof. Fulton, and, indeed, much of it is entirely rewritten on modern lines by experts in the various branches of the subject. The contributors are numerous, for in addition to text written by the editors there are considerable contributions by J. Russell Elkinton, John H. Ferguson, Robert G. Grenell, William F. Hamilton, Ebbe C. Hoff, Hebbel E. Hoff, Chas. W. Hooker, Walter Landauer, Harry D. Patton, Robert F. Pitts, Eric Ponder, Frank W. Weymouth, and Alfred E. Wilhelm, making a total of 24 contributors. The production is thus thoroughly composite in character, and the task of editing must have been correspondingly heavy. It seems, however, to have been done as efficiently as could have been desired, and to give a correct picture of modern American physiology. It is prefaced by a short account of the historical background of American physiology which closes with the significant words: "When peace came again every physiologist who has the future of his subject at heart will hope to pursue the science for its own sake, even as Howell pursued it during sixty-five years of unremitting endeavour—an endeavour dedicated in the first instance to physiology pure and unapplied."

The book can be recommended as a reliable work of reference dealing with physiology in its most modern aspects: the biochemical portions, though adequate and up-to-date, are less fully treated than the more biological portions of the text. There is stress on biophysics, and perhaps relatively too much space is taken up by the chapters dealing with the nervous system and the special senses, which, with muscle and nerve, occupy nearly 540 pages. There are no chapters devoted to the endocrine organs, references to which merely crop up incidentally in the other sections. The whole book is authoritative and will be of value to British physiologists and to advanced students. The print and illustrations are excellent.

Notes on Books

The New York Tuberculosis and Health Association (386, Fourth Avenue, New York 16) has published as a volume in typescript *Tuberculosis Reference Statistical Yearbook* for the year 1944, with comparative summaries for 1943 and the five-year period 1940-1944. The contents include a summary of morbidity and mortality from tuberculosis in New York and New Jersey, the large American cities of the United States generally, Canada, and selected European capitals and countries, and also clinic reports from New York City.

A list of scientific institutions, societies, and research workers in the Netherlands Indies has been reprinted as a pamphlet from *Science and Scientists in the Netherlands Indies*, which was noticed in the columns on March 30, 1946 (p. 488). Copies of this reprint may be obtained without charge by writing to the Library, Board for Netherlands Indies, Surinam and Curaçao, 10, Rockefeller Plaza, 14th Floor, New York 20, or to the Editor of *Chronica Botanica*, P.O. Box 1: Waltham 54, Mass., U.S.A.

The *Dentists Register* for 1946 has now been published for the Dental Board of the United Kingdom by Constable and Co., 10, Abchurch Lane, London, E.C.4, price 15s. The total number of names appearing at the end of last year was 15,422—16 less than the figure for 1944. All but one of the new entries were of persons registered as graduates or licentiates.
